

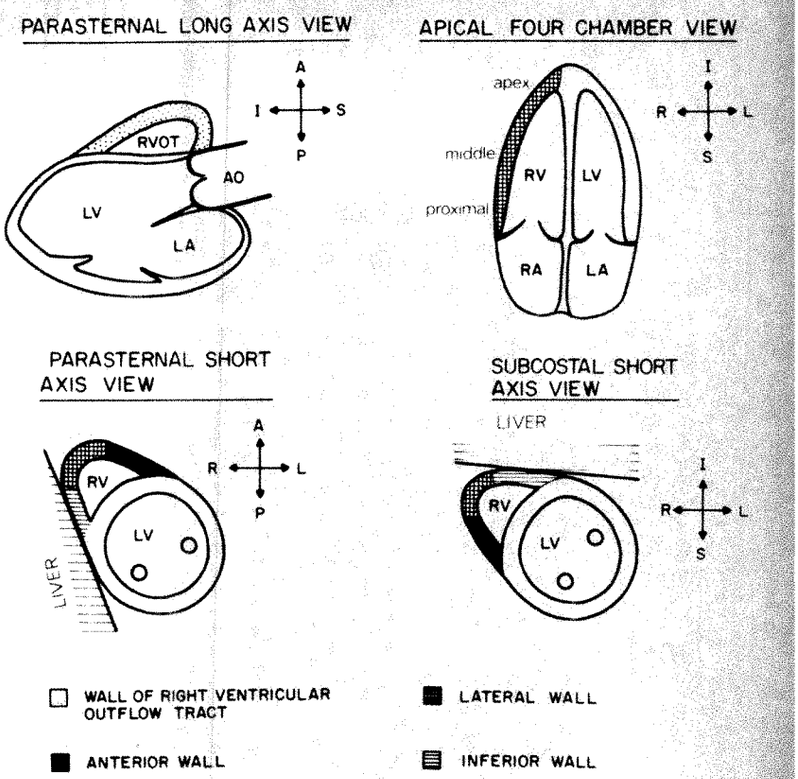

**FIGURE 1.** Schematic representation of the different echocardiographic views studied. A = anterior; AO = aorta; I = inferior; L = left; LA = left atrium; LV = left ventricle; P = posterior; R = right; RA = right atrium; RV = right ventricle; RVOT = right ventricular outflow tract; S = superior.

and aVF. "Anterior" MI was defined by the presence of abnormal Q waves in 2 or more adjacent precordial leads ($V_1$-$V_6$).

The study was initially begun including only those patients with acute posterior MI in whom hemodynamic monitoring had been performed. However, because 2 patients with acute anterior MI were found to have hemodynamic criteria of ischemic RV dysfunction, a group of 5 additional unselected patients with acute anterior MI were included.

Patients with acute MI without hemodynamic monitoring were not included. Patients with previously known MI, chronic congestive failure, pericardial disease, valvular heart disease, or chronic obstructive lung disease were not included. Of the initial 70 patients, 7 were excluded because of failure to obtain satisfactory 2-D echocardiograms of the right ventricle in at least 1 transversal plane (parasternal or subcostal short-axis views). Thus, a total of 63 patients (52 men, and 11 women, aged 36 to 78 years) were included.

**Hemodynamic monitoring:** Hemodynamic monitoring was performed in all patients. Right atrial, pulmonary artery, and pulmonary capillary wedge pressures were recorded in millimeters of mercury with a Hewlett-Packard 1280 transducer on a Siemens Elema Mingograph 34 through a Swan-Ganz thermodilution catheter.

Hemodynamic determinations were made at least every 8 hours. Monitoring was begun at admission and maintained for 3 to 5 days, being discontinued when the condition of the patient was considered as stable (subset I or II according to Forrester[10]) and had no hemodynamic variations for at least 24 hours.

**Criteria of RV dysfunction:** The diagnosis of ischemic RV dysfunction was made when the relation between right atrial and pulmonary capillary pressure was indicative of primary RV dysfunction, according to the results of a previous study.[11] Although this relation varies according to the level of pulmonary capillary pressure, for practical purposes right atrial mean pressure must be >10 mm Hg and either greater than, equal to, or not more than 5 mm Hg less than pulmonary capillary pressure. This criterion was found sensitive (73%) and very specific (100%) for the diagnosis of acute RV MI.[11] In patients with a right atrial pressure <10 mm Hg in the absence of pulmonary congestion, a volume loading test with dextran 40 was performed to identify ischemic RV dysfunction not present in basal conditions.[11,12]

**Echocardiographic examination:** Real-time 2-D echocardiographic examination was performed with the patient in the supine position or 30° to 60° left lateral decubitus using a wide angle (90°) mechanical sector scanner (Mark III, Advanced Technology Laboratory) and a 3 MHz transducer. Echocardiograms were obtained 3 to 12 hours after the last hemodynamic determination. In this period of time, the clinical condition of the patients included in the study was considered stable, without episodes of pain, dyspnea, arrhythmias, or variations in blood pressure.

Visualization of the ventricles and the ventricular septum in the long-axis, 4-chamber, and short-axis planes was obtained from parasternal, apical, and subcostal positions. Transverse planes were obtained from both parasternal and subcostal positions. All echocardiographic recordings were obtained in normal (90°) and amplified (45°) dimensions, and stored on a Sanyo VJC 7100 tape recording system. Individual frames selected for the figures were photographed using a Polaroid® film from the videotape. There was significant degradation of the stop frame image because only 1 of the 2 fields could be visualized.

A simultaneous electrocardiogram was recorded. The initiation of the QRS complex was used as an end-diastolic marker, and the end of systole was assumed to correspond to the end of the T wave. Imaging of the endocardial outline was obtained by playing through preceding and succeeding beats, using both real-time and slow motion playback.

Only RV free wall and ventricular septal motion were considered. The RV wall was divided into several segments (Fig. 1), and each was analyzed for wall motion abnormalities. Wall motion was qualitatively classified as *normal* (inward motion of the endocardium during systole) (Fig. 2), *akinetic* (absence of motion) (Fig. 3), or *dyskinetic* (outward motion of the endocardium during systole) (Fig. 4 and 5). Ventricular septal motion was considered as normal when the septum was displaced toward the left ventricular cavity in systole, akinetic when no septal movement could be appreciated, and dyskinetic or paradoxical when both sides of the septum were displaced toward the RV cavity during systole (Fig. 4 and 5).

All echocardiograms were interpreted independently by 2 observers, without previous knowledge of the hemodynamic data of each patient. In case of discrepancy, the studies were reviewed and an agreement was reached.

**Groups:** The patients were classified into 2 groups: *Group A* included 32 patients with definite ischemic RV dysfunction in at least 1 hemodynamic determination during the monitoring period. Nineteen of the 32 patients had a relation between right atrial and pulmonary capillary pressures indicative of ischemic RV dysfunction at the time of the echocardiographic examination (Group AI); The 13 remaining patients had transient ischemic RV dysfunction with a normal pressure relation at the time of the echocardiographic study (Group AII). Twenty-two patients had electrocardiographic evidence of posterior MI, 2 of anterior MI, and 8 of posterior plus anterior MI. *Group B* included 31 patients without hemodynamic criteria of ischemic RV dysfunction during the entire period of hemodynamic monitoring. Acute MI was posterior in 20 patients, anterior in 5, and posterior plus anterior in 6.

**Statistical analysis:** All statistical analyses were performed using nonparametric tests: chi-square test and Fisher's exact test. Significant values were considered those corresponding to $p < 0.05$. Only hemodynamic data corresponding to the last hemodynamic determination before the echocardiographic examination were considered for statistical analysis.

## Results

**Hemodynamic findings:** By definition, only Group A patients had a right atrial-pulmonary capillary pressure relation indicative of ischemic RV dysfunction. In all patients from Group AI, ischemic RV dysfunction was spontaneous, whereas in 5 patients from Group B it was observed only after volume loading.

**Two-D echocardiographic findings: Right ventricular segmental wall motion:** The number of patients with asynergy and the number of segments with abnormal wall motion found in each group in the different echocardiographic views are shown in Table I.

*Transverse plane:* Regional abnormalities in segmental wall motion were observed in 29 patients: 19 in Group AI, 7 in Group AII, and 3 in Group B. (Fig. 3 and 4).

When subcostal and parasternal views were compared, no difference was found in either the number of patients with wall motion abnormalities, the number of segments with asynergy, or the type of asynergy, between both short-axis views obtained. However, 2 patients had akinesia of the inferior RV wall in the subcostal short-axis view although the movement of these segments was considered normal in the parasternal short-axis view. Good quality images of the subcostal transversal plane were obtained in 62 patients; adequate imaging of the parasternal transversal plane could only be obtained in 42 patients.

In the longitudinal parasternal view, dyskinesia of the RV outflow tract was observed in 1 patient (Group AI). In the remaining 50 patients in whom good quality echocardiographic images were obtained, contraction of the RV outflow tract was normal.

In the *apical 4-chamber view*, asynergy of the lateral RV wall occurred in 9 patients (Fig. 5), 8 of whom were in Group AI. In the other patient, included in Group AII, akinesia of the RV apex was the only abnormality.

**Ventricular septal motion:** In Group A, septal motion was normal in 18 patients (56%), akinetic in 5 (16%), and dyskinetic in 9 (28%). Paradoxical motion of the ventricular septum was always accompanied by some alteration in the movement of the RV posterior wall ($p < 0.001$) (Fig. 4). In group B, septal motion was normal in 24 patients (77%), and akinetic in the remaining 7 (23%).

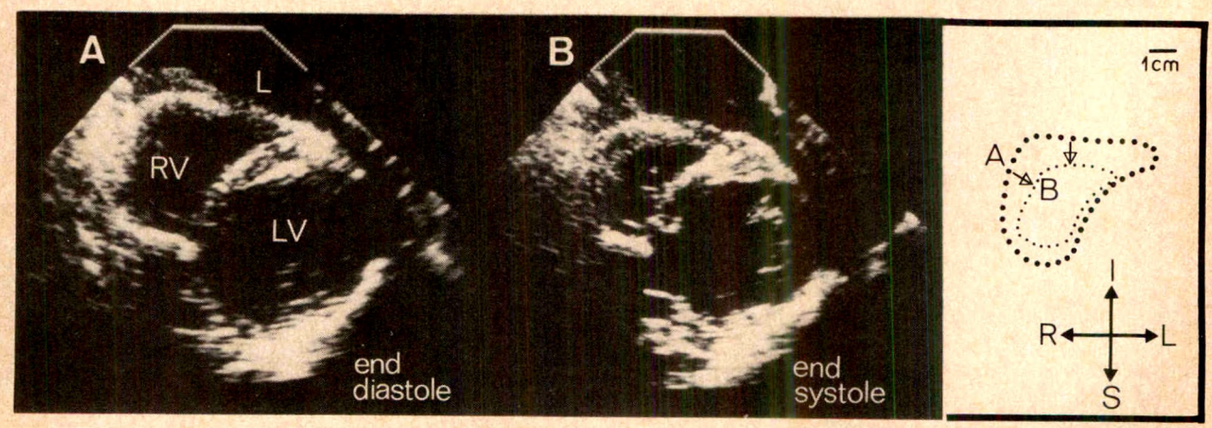

**FIGURE 2.** Subcostal short-axis view of both ventricles. Normal motion of the RV wall and interventricular septum. L = liver or lateral; other abbreviations as in Figure 1.

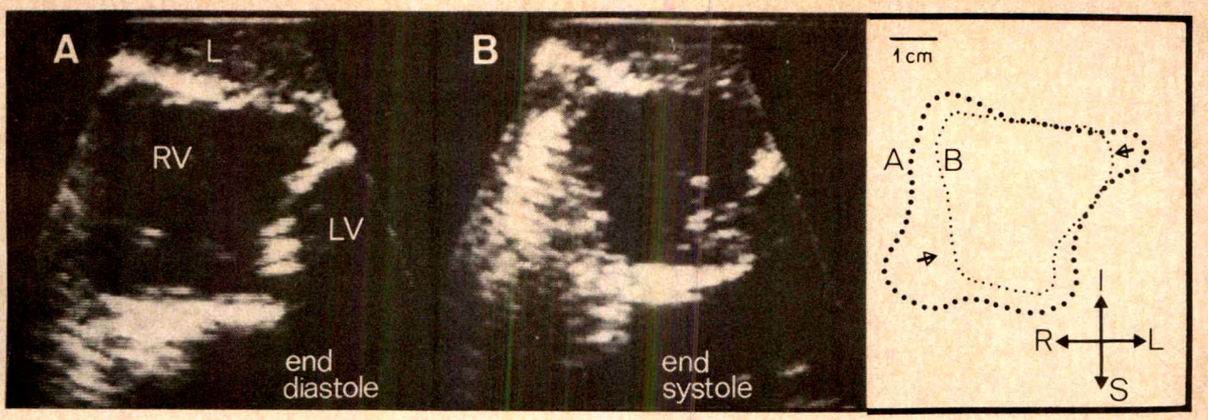

**FIGURE 3.** Subcostal short-axis view: akinesia of the inferior RV wall. Abbreviations as before.

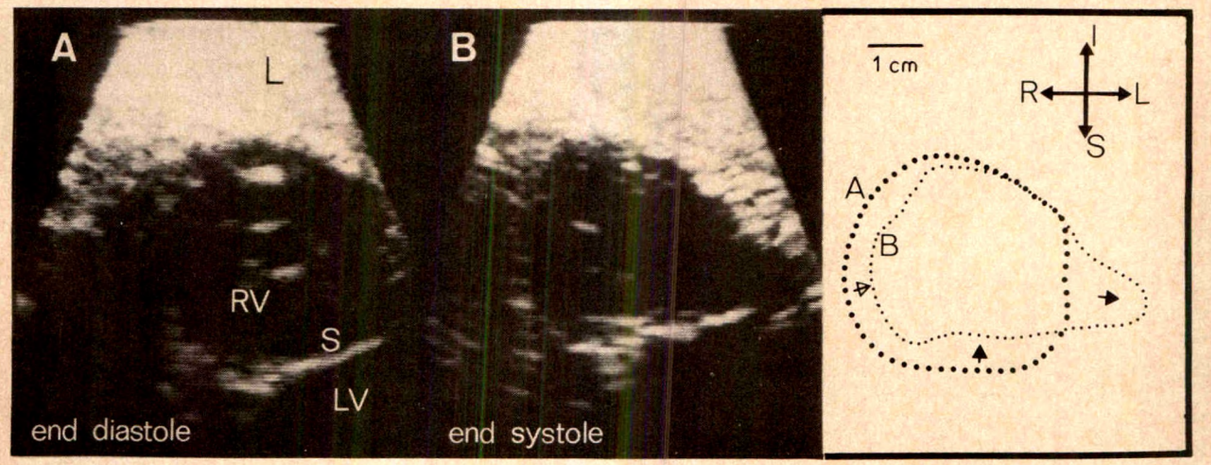

**FIGURE 4.** Subcostal short-axis view: dyskinesia of the inferior RV wall adjacent to the interventricular septum. Paradoxical septal motion. **Open arrows,** normal contraction. **Solid arrows,** dyskinesia. S = interventricular septum or superior; other abbreviations as before.

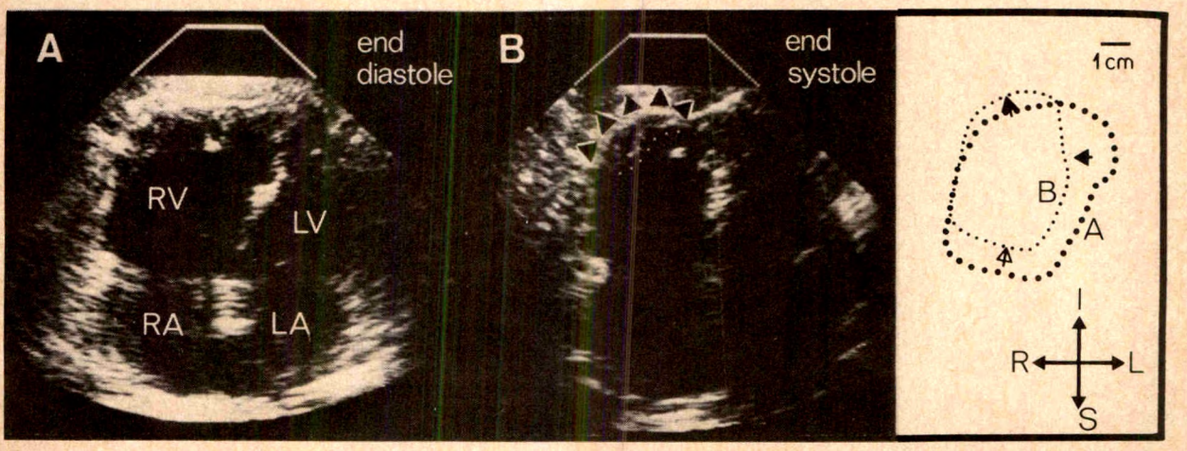

**FIGURE 5.** Apical 4-chamber view: dyskinesia of the RV apex. Paradoxical septal motion. A thrombus can be identified in the RV apex. Abbreviations as before.

**TABLE I Frequency of Asynergy in the Different Groups: RV Wall Motion**

| | All 2-D Echocardiographic Views | | Number of Segments With Asynergy | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | Transverse View | | | | Four-Chamber View | | | | Long-Axis View | |
| Patients | Normal | Asynergy | 0 | 1 | 2 | 3 | 0 | 1 | 2 | 3 | 0 | 1 |
| | | | | | | Group AI | | | | | | |
| N | 0 | 19 | 0 | 7 | 8 | 4 | 7 | 5 | 3 | 0 | 15 | 1 |
| % | ... | 100 | ... | 37 | 42 | 21 | 47 | 33 | 20 | ... | 94 | 6 |
| | | | | | | Group AII | | | | | | |
| N | 5 | 8 | 6 | 7 | 0 | 0 | 11 | 1 | 0 | 0 | 13 | 0 |
| % | 38.5 | 61.5 | 46 | 54 | ... | ... | 91.7 | 8.3 | ... | ... | 100 | ... |
| | | | | | | Group B | | | | | | |
| N | 28 | 3 | 28 | 2 | 1 | 0 | 28 | 0 | 0 | 0 | 22 | 0 |
| % | 90 | 10 | 90 | 6 | 3 | ... | 100 | ... | ... | ... | 100 | ... |
| | $p < 0.001$ | | | $p < 0.001$ | | | | $p < 0.001$ | | | | |

**Correlation between hemodynamics and 2-D echocardiographic findings:** *Right ventricular wall:* A significant relation was found between hemodynamic data of ischemic RV dysfunction and alterations in segmental RV wall motion. A highly significant difference was found either in the frequency of wall motion abnormalities or the number of segments with asynergy among the 3 groups of patients ($p < 0.001$) (Table I). Furthermore, a highly significant difference was also found between the incidence and number of segments with abnormal wall motion and the presence of a right atrial pressure equal to or greater than the pulmonary capillary pressure ($p < 0.001$) (Table II), indicating that the severity of asynergy is related to the severity of ischemic RV dysfunction.

*Ventricular septum:* A significant relation was found between the presence of dyskinetic or paradoxical septal motion and the hemodynamic data indicative of ischemic RV dysfunction ($p < 0.001$). All 9 patients with paradoxical septal motion were included in Group AI and all had a right atrial pressure equal to or higher than pulmonary capillary pressure. However, 2 patients without paradoxical septal motion also had a right atrial pressure equal to or greater than pulmonary capillary pressure when the echocardiographic examination was performed.

**TABLE II Frequency of Asynergy in Relation to Hemodynamic Data**

| | Number of Segments With Asynergy | | |
|---|---|---|---|
| | 0 | 1 | 2 |
| RAP <PCP | | | |
| Number of patients | 0 | 2 | 9 |
| Percent | ... | 3 | 14 |
| RAP ≥PCP | | | |
| Number of patients | 33 | 14 | 5 |
| Percent | 52 | 22 | 8 |
| | | $p < 0.001$ | |

PCP = pulmonary capillary pressure; RAP = right atrial pressure.

## Discussion

**Segmental RV contraction in acute MI:** Asynergy of the RV wall has been reported in patients with RV MI.[2,5–9] Our results demonstrate that abnormalities in segmental RV wall motion are common in patients with acute MI and can easily be appreciated by 2-D echocardiography. The actual frequency of such abnormalities cannot be accurately defined from this study because not all patients with acute MI admitted to the coronary care unit were included.

Although acute RV infarction is generally associated with posterior left ventricular infarction,[11,13] a small number of patients with anterior MI also had RV asynergy, correlating well with hemodynamic alterations consistent with ischemic RV dysfunction.

Asynergy may be identified in all segments of the RV wall, including the outflow tract, ventricular apex, and the anterior wall, but is, in general, specifically located in the posterior RV wall. Asynergy of other regions without posterior wall involvement is rare, and in this study was found in only 1 patient. Moreover, anatomicopathologic studies indicate that in most cases, RV infarctions are confined to the posterior RV wall[11,13] which can be identified only in the transversal plane. The transversal plane is the most useful echocardiographic view for the identification of such abnormalities.

The greater frequency of wall motion abnormalities in the long-axis and 4-chamber planes reported in previous studies[8,9] can be attributed to a more rigid criteria of patient selection, inclusion being restricted to patients with strong clinical evidence of RV infarction.

**Segmental RV contraction and RV infarction:** Recent echocardiographic and anatomic studies[3,4] demonstrated that necrotic segments of the left ventricle almost always present motion abnormalities, but the latter far less frequently imply MI, and a number of nonnecrotic myocardial segments show segmental wall motion abnormalities. # Designed to achieve your therapeutic goals in hypertension

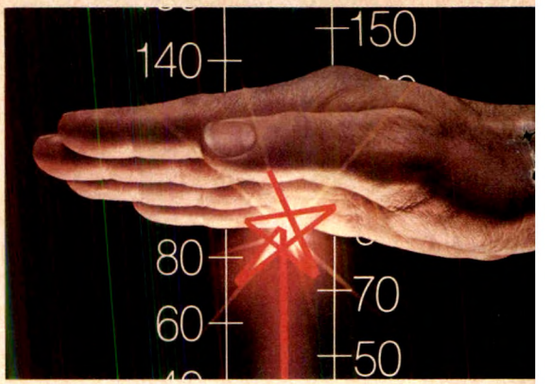
ACE* INHIBITOR

# CAPOTEN® (captopril tablets)

For hypertensive patients

- **Who experience unacceptable side effects with beta blockers, antiadrenergic agents, or vasodilators**
- **In whom standard multidrug regimens are ineffective in controlling blood pressure**
- **Who have concomitant conditions contraindicating use of other antihypertensive agents**



*Angiotensin Converting Enzyme

SQUIBB

See last pages of this advertisement for brief summary.

ACE* INHIBITOR

# CAPOTEN®
## (captopril tablets)

**CAPOTEN controls blood pressure without the following usual antihypertensive side effects†:**

- No cardiac depression
- No glucose intolerance
- No bradycardia
- No mental depression
- No sleep disturbances
- No nasal congestion
- No hypokalemia
- Rare impotence/loss of libido
- Rare bronchospasm
- Rare tachycardia
- Rare fatigue

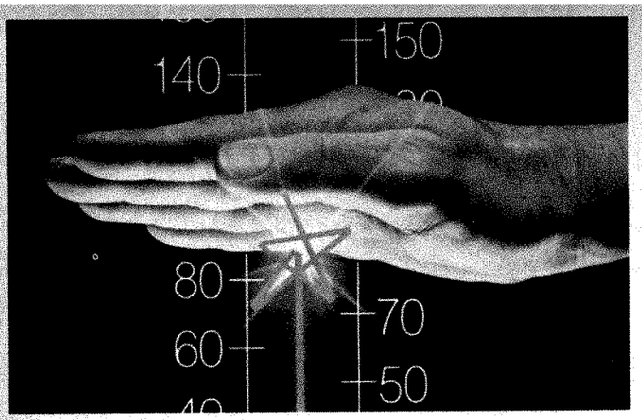
## CAPOTEN is appropriate therapy when coexisting disorders complicate hypertension management

Unlike some other antihypertensive agents, CAPOTEN is appropriate for use in the presence of a wide range of cardiovascular and metabolic disorders that often coexist with hypertension.

- Bronchospastic disease
- Cardiac arrhythmias
- Congestive heart failure
- Diabetes mellitus
- Hepatic disease

## CAPOTEN is effective in controlling many kinds of hypertension when conventional multidrug regimens have proven inadequate

- Essential hypertension
- Hypertension resistant to standard triple therapy (STT)
- Hypertension associated with low, normal, and high plasma renin levels
- Renovascular hypertension



ACE* INHIBITOR

# CAPOTEN®
## (captopril tablets)

*Angiotensin Converting Enzyme

† Please see brief summary of prescribing information on the last pages of this advertisement for INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS.

ACE* INHIBITOR

# CAPOTEN®
# (captopril tablets)

**CAPOTEN has been associated with the development of neutropenia, agranulocytosis, or proteinuria.† These serious side effects are more likely to occur in patients with predisposing conditions, such as renal impairment or autoimmune disease, or in patients receiving therapy known to suppress the autoimmune response.**

**The following precautionary guidelines are recommended for all patients receiving CAPOTEN:**

- **Obtain urinary protein level estimates prior to initiating therapy, at monthly intervals for the first nine months of treatment, and periodically thereafter.**
- **Obtain WBC counts at the initiation of therapy, at two-week intervals for the first three months of treatment, and periodically thereafter.**
- **Carefully review the WARNINGS and ADVERSE REACTIONS sections in the complete prescribing information, with particular attention to the patient at increased risk.**
- **The most frequently occurring adverse reactions are skin rash and taste alteration; both effects are generally mild, reversible, or self-limited.**

SQUIBB®

*Angiotensin Converting Enzyme

† Please see brief summary of prescribing information, for INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS.

**CAPOTEN® TABLETS**
**Captopril Tablets**

**INDICATIONS: Hypertension —** Because serious adverse effects have been reported (see WARNINGS), CAPOTEN is indicated for treatment of hypertensive patients who on multidrug regimens have either failed to respond satisfactorily or developed unacceptable side effects.
**Heart Failure:** CAPOTEN (captopril) is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.
**WARNINGS: Proteinuria —** Total urinary proteins >1 g/day were seen in 1.2% of patients on captopril; the nephrotic syndrome occurred in about ¼th of these cases. About 60% of affected patients had evidence of prior renal disease; the remainder had no known renal dysfunction. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients.
Membranous glomerulopathy was found in nearly all the proteinuric patients on captopril who were biopsied and may be drug related. Most cases of proteinuria occurred by the 8th month of therapy. Patients should have urinary protein estimates (dip-stick on 1st morning urine, or quantitative 24-hr urine — the latter provides greater precision when proteinuria is persistent and/or at low levels) before therapy, at approx. monthly intervals for the 1st 9 months of therapy, and periodically thereafter. For patients who develop proteinuria >1 g/day, or increasing proteinuria, the benefits and risks of continuing captopril should be evaluated.
**Neutropenia/Agranulocytosis —** Neutropenia (<300/mm³) associated with myeloid hypoplasia (probably drug related) occurred in about 0.3% of captopril treated patients. About half of the neutropenic patients developed systemic or oral cavity infections or other features of agranulocytosis. Most of the neutropenic patients had severe hypertension and renal function impairment; about half had systemic lupus erythematosus (SLE), or another autoimmune/collagen disorder; multiple concomitant drug therapy was common, including immunosuppressive therapy in a few cases. Daily doses of captopril in the leukopenic patients were relatively high, particularly in view of their diminished renal function. The neutropenia appeared 3 to 12 weeks after starting captopril; it developed relatively slowly, taking 10 to 30 days to have white blood count fall to its nadir; neutrophils returned to normal in about 2 weeks (other than 2 patients who died of sepsis).
**Use captopril with caution in patients with impaired renal function, serious autoimmune disease (particularly SLE), or who are exposed to other drugs known to affect the white cells or immune response. In patients at particular risk (as noted above), perform white blood cell and differential counts prior to therapy, at about 2-week intervals for about the 1st 3 months of therapy, and periodically thereafter.**
The risk of neutropenia in patients who are less seriously ill or who receive lower dosages appears to be smaller. In these patients white blood cell counts should be performed every 2 weeks for the 1st 3 months of therapy, and periodically thereafter. Perform differential counts when leukocytes are <4000/mm³ or the pretherapy white count is halved. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat; fever), if infection is suspected, perform counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count <1000/mm³) withdraw captopril and closely follow the patient's course.
**Hypotension —** Excessive hypotension was rarely seen in hypertensive patients but is a possibility in severely salt/volume-depleted persons such as those treated vigorously with diuretics (see PRECAUTIONS [Drug Interactions]).
In heart failure, where blood pressure was either normal or low, transient decreases in blood pressure >20% were recorded in about ½ the patients. This transient hypotension may occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.
**BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.**
**PRECAUTION: General:** *Impaired Renal Function.* Hypertension — Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure — About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Valvular Stenosis* — A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis, due to decreased afterload reduction.
*Surgery/Anesthesia* — If hypotension occurs during major surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.
**Drug Interactions:** *Hypotension: Patients on Diuretic Therapy* — Precipitous reduction of blood pressure may occasionally occur within the 1st 3 hours after administration of the initial captopril dose in patients on diuretics, especially those recently placed on diuretics and those on severe dietary salt restriction or dialysis. This possibility can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy. Alternatively, provide medical supervision for at least 3 hours after the initial dose in hypertensive patients.
*Agents Having Vasodilator Activity:* In heart failure patients vasodilators should be administered with caution.
*Agents Causing Renin Release* — Captopril's effect will be augmented by

(Continued on next page.)

(continued from preceding page)

antihypertensive agents that cause renin release.

*Agents Affecting Sympathetic Activity* — The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

*Agents Increasing Serum Potassium* — Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium.

**Drug/Laboratory Test Interaction:** Captopril may cause a false-positive urine test for acetone.

**Carcinogenesis, Mutagenesis, and Impairment of Fertility:** Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential. Studies in rats have revealed no impairment of fertility.

**Usage in Pregnancy:** There are no adequate and well-controlled studies in pregnant women. Embryocidal effects were observed in rabbits. Therefore, captopril should be used during pregnancy only if the potential benefit outweighs the potential risk to the fetus.

**Nursing Mothers:** Captopril is secreted in human milk. Exercise caution when administering captopril to a nursing woman, and, in general, nursing should be interrupted.

**Pediatric Use:** Safety and effectiveness in children have not been established although there is limited experience with use of captopril in children from 2 months to 15 years of age. Dosage, on a weight basis, was comparable to that used in adults. Captopril should be used in children only if other measures for controlling blood pressure have not been effective.

**ADVERSE REACTIONS:** Reported incidences are based on clinical trials involving about 4000 patients.

*Renal* — One to 2 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients.

*Hematologic* — Neutropenia/agranulocytosis occurred in about 0.3% of captopril treated patients (see WARNINGS). Two of these patients developed sepsis and died.

*Dermatologic* — Rash (usually mild, maculopapular, rarely urticarial), often with pruritus and sometimes with fever and eosinophilia, in about 10 of 100 patients, usually during the 1st 4 weeks of therapy. Pruritus, without rash, in about 2 of 100 patients. A reversible associated pemphigoid-like lesion, and photosensitivity have also been reported. Angioedema of the face, mucous membranes of the mouth, or of the extremities in about 1 of 100 patients — reversible on discontinuance of captopril therapy. One case of laryngeal edema reported. Flushing or pallor in 2 to 5 of 1000 patients.

*Cardiovascular* — Hypotension in about 2 of 100 patients. See WARNINGS (Hypotension) and PRECAUTIONS (Drug Interactions) for discussion of hypotension on initiation of captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1000 patients.

*Dysgeusia* — About 7 of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months). Gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, and paresthesias reported in about 0.5 to 2% of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials.

**Altered Laboratory Findings:** Elevations of liver enzymes in a few patients although no causal relationship has been established. Rarely cholestatic jaundice and hepatocellular injury with secondary cholestasis have been reported. A transient elevation of BUN and serum creatinine may occur, especially in volume-depleted or renovascular hypertensive patients. In instances of rapid reduction of longstanding or severely elevated blood pressure, the glomerular filtration rate may decrease transiently, also resulting in transient rises in serum creatinine and BUN. Small increases in serum potassium concentration frequently occur, especially in patients with renal impairment (see PRECAUTIONS).

**OVERDOSAGE:** Primary concern in correction of hypotension. Volume expansion with an I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure. Captopril may be removed from the general circulation by hemodialysis.

**DOSAGE AND ADMINISTRATION:** CAPOTEN should be taken one hour before meals. Dosage must be individualized; see DOSAGE AND ADMINISTRATION section of package insert for detailed information regarding dosage in hypertension and in heart failure. Because CAPOTEN (captopril) is excreted primarily by the kidneys, dosage adjustments are recommended for patients with impaired renal function.

**Consult package insert before prescribing CAPOTEN (captopril).**

**HOW SUPPLIED:** Available in tablets of 25, 50, and 100 mg in bottles of 100, and in UNIMATIC® unit-dose packs of 100 tablets.

## What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

## CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

***"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."*** Philip Reichert, M.D. New York State Journal of Medicine, September, 1981

***"...recommend...to any reader interested in the literature of cardiology."*** Irwin R. Callen, M.D. JAMA, November, 1981

**SPECIAL DISCOUNT OFFER**

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

☐ **YES,** please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

**Yorke Medical Books,** Box C-757, Brooklyn, NY 11205 AJCB3

☐ Please send me a copy of the 1982 edition at the full price of $45.00. I do not wish to place a standing order.

☐ Enclosed is my check for _____. Yorke pays postage and handling. (Same return privilege)
(New York residents add appropriate sales tax. Add $5.00 per book for orders outside the U.S. and Canada.)

☐ Please bill my ☐ VISA ☐ MasterCard (same return privilege)

# Dialog of the Hearts –by Hemingway:

"And she smiled and from no distance said, 'Hello, my Inglés.'

'I'm not an Inglés', he said very lazily.

'Oh yes, you are', she said. 'You're my Inglés', and reached and took hold of both his ears and kissed him on the forehead.

'There', she said. 'How is that? Do I kiss thee better?'

Then they were walking along the stream together and he said, 'Maria, I love thee and thou art so lovely and so wonderful and so beautiful and it does such things to me to be with thee that I feel as though I wanted to die when I am loving thee'.

'Oh', she said. 'I die each time. Do you not die?'

'No. Almost. But did thee feel the earth move?'

'Yes. As I died. Put thy arm around me, please'.

'No. I have thy hand. Thy hand is enough".

The Dialogue of Robert Jordan and Maria from "For Whom the Bell Tolls".

# Variable Threshold Exertional Angina in Patients With Transient Vasospastic Myocardial Ischemia

## Repeat Exercise Test Results and Therapeutic Implications

STEFANO DE SERVI, MD, GIUSEPPE SPECCHIA, MD, COLOMBA FALCONE, MD, ANTONELLO GAVAZZI, MD, ANTONIO MUSSINI, MD, LUIGI ANGOLI, MD, EZIO BRAMUCCI, MD, DIEGO ARDISSINO, MD, LAURA VACCARI, MD, JORGE SALERNO, MD, and PIERO BOBBA, MD

**Thirty-five of 70 patients with vasospastic angina at rest complained of chest pain during exercise or during usual daily activity. In 22, the angina threshold was described as variable during exercise: that is, the amount of exertion that induced angina was not always the same. In 12 patients with variable threshold exertional angina, 3 exercise tests performed in the morning on different days yielded different results, because chest pain and ischemic electrocardiographic changes occurred at different work loads with a wide range in heart rate-systolic pressure product. Two patients, in whom great cardiac vein flow was measured during exercise before and after taking nifedipine, tolerated heavier work loads after receiving the drug, with a more marked increase in flow during exercise. It is concluded that variable threshold exertional angina can be objectively demonstrated by repeat exercise tests in patients with vasospastic angina. Variability of the angina threshold may be due to a functional mechanism that causes myocardial ischemia in addition to the increased myocardial metabolic requirements provoked by exercise. Because in such patients fluctuations in coronary arterial tone play an important role in determining the response to exercise, calcium antagonistic drugs, which lower coronary tone and prevent the occurrence of coronary spasm, are effective in increasing exercise capacity.**

Patients with vasospastic angina at rest may also have chest pain during exercise or during usual daily activity.[1,2] In these patients the angina threshold may vary from time to time; a few patients have recently been described[3–5] in whom repeated exercise tests induced myocardial ischemia at different values of heart rate-systolic blood pressure product, an index of myocardial oxygen consumption.[6] However, the incidence of this phenomenon is not yet appreciated, and it is not clear whether the clinical suspicion of variable threshold exertional angina can always be confirmed by repeated exercise tests.

From the Divisione di Cardiologia, Cattedra di Fisiopatologia Cardiorespiratoria, Policlinico S. Matteo, Pavia, Italy. Manuscript received March 30, 1982; revised manuscript received July 20, 1982; accepted July 23, 1982.

Address for reprints: Stefano de Servi, MD, Divisione di Cardiologia, Policlinico S. Matteo, 27100 Pavia, Italy.

This study describes the results of repeated exercise tests in patients with vasospastic angina presenting with this clinical manifestation. We believe that the recognition of variable threshold exertional angina may have important therapeutic implications.

### Methods

**Patients: Criteria of selection:** Between October 1979 and October 1981 we observed 70 patients with vasospastic angina at rest without evidence of previous transmural myocardial infarction. Coronary vasospasm was considerd responsible for the occurrence of chest pain at rest on the basis of the following criteria: Sixty patients showed transient S-T segment elevation during at least 1 episode of chest pain at rest,[7] whereas the remaining 10 patients showed S-T segment depression repeatedly during chest pain as well as after the administration of intravenous ergonovine maleate in the coronary care unit.[14,15] Thirty-five patients also complained of chest pain during exercise or usual daily activity. In 22 of these patients the angina threshold was described as variable dur

Ang = angina; ECG = electrocardiographic; Exh = exhaustion; RPP = heart rate-systolic pressure product, mm Hg × beats/min × $10^{-2}$; ↑S-T = S-T segment elevation; ↓ST = S-T segment depression; — = no electrocardiographic changes.

exercise; these patients could not recognize a critical amount of exertion they could perform before experiencing angina but the level of activity that determined the symptoms varied from time to time. Twelve of these 22 patients were selected for this study. The selection was not done in a random fashion but depended on the clinical characteristics of the patients. We excluded patients with more than 3 episodes of chest pain at rest per day or with severe ventricular arrhythmias or left ventricular failure during anginal attacks.[16] In the 12 patients studied, drug therapy consisting of nitrates and nifedipine could be suspended 12 hours before exercise tests without any manifestation of withdrawal phenomena, such as accelerated angina or other coronary events. No patient was receiving beta-adrenergic blocking agents or digitalis.

**Exercise testing:** The 12 patients selected performed 3 bicycle exercise tests in the morning (8:30 to 11:00 A.M.) on different days during hospitalization. The mean interval between the first and the third exercise test was 7.8 ± 6 days. Two of these patients were described recently.[3] The exercise tests were performed in the supine position with an initial work load of 50 W and subsequent increments of 25 W every 3 minutes. Exercise was stopped when angina, dyspnea, exhaustion, S-T segment elevation ≥2 mm, or S-T segment depression >3 mm occurred. A 12-lead electrocardiogram was taken before and at the end of exercise, and every minute during recovery; leads $V_4$, $V_5$, and $V_6$ were monitored during exercise. Cuff blood pressure was measured at 3-minute intervals. The criteria for a positive exercise test were a horizontal or downsloping S-T segment depression ≥1 mm for 0.08 second compared with the resting tracing and S-T segment elevation ≥1 mm at 0.04 second after the J point compared with *the baseline* electrocardiogram. An estimate of myocardial oxygen consumption was made from the double product, obtained by multiplying systolic arterial pressure and heart [illegible].[6]

**Coronary arteriography:** The 12 patients studied underwent coronary arteriography using the Sones technique after premedication with 10 mg of diazepam. Left ventriculography was performed in the right anterior oblique projection before arteriography. Narrowing >50% of 1 or more coronary arteries was considered evidence of significant coronary artery disease. When a significant lesion was noted, the vessel was filmed again after sublingual administration of nitroglycerin.

**Coronary flow study:** In 2 patients with isolated left anterior descending artery disease, exercise tests were performed before and 20 minutes after sublingual administration of 20

**TABLE II Electrocardiographic (ECG) Changes During Chest Pain at Rest and Coronary Arteriographic Findings**

| Case | Age (yr) & Sex | ECG Changes (Spontaneous Angina) | Coronary Arteriographic Findings |

mg of nifedipine; the tests were done with the patient in the supine position with an initial work load of subsequent increments of 25 W every 3 minutes. A triple thermistor thermodilution catheter (Wilton Webster Laboratories, Altadena, California) was inserted into the coronary sinus with the tip advanced to the great cardiac vein, so that the flow recorded was entirely from the great cardiac vein.[17] Its position was confirmed with fluoroscopy and frequently checked throughout the procedure. Flow measurements were obtained in basal conditions and at peak exercise[15,18] by injecting physiologic saline solution at 24° per 30 seconds using a pump at a rate of 56 ml/min. The left brachial artery was punctured to measure intraarterial pressure.

An interval of 30 minutes was allowed to elapse between the end of the first exercise test and the administration of nifedipine. Great cardiac vein flow (GCVF) was calculated using the following formula: $GCVF = V_i \times [(T_b - T_i)/(T_b - T_m) - 1] \times 1.08$, where $V_i$ represents the volume of injectate (ml/min) and $T_b$, $T_i$, and $T_m$ the temperatures of blood, injectate, and mixture of blood and injectate; 1.08 is a constant of the saline solution.

Informed consent was obtained from all patients before each test. No complications were observed during the procedures.

## Results

**Clinical features:** Eleven patients were men and 1 a woman, with an average age of 52.7 years (range 38 to 62). In 8 patients, anginal attacks at rest were associated with S-T segment elevation, occurring in the anterior leads in 4 patients and in the inferior leads in 4, whereas 1 patient had episodes associated with either S-T segment elevation or depression in the anterior leads. Three patients showed S-T segment depression in the anterior leads during chest pain at rest. In 6 patients, angina was of recent onset (<3 months).

**Exercise tests (Table I):** Four patients (Cases 2, 4, 7, and 10) had 1 negative test and 2 positive tests; 1 patient (Case 3) had 2 negative tests and 1 positive test. Seven patients had all 3 positive tests. Chest pain occurred during all 3 exercise tests in 3 patients, while 8 patients had at least 1 exercise test ended because of exhaustion. In 1 patient the end point was angina in 2 tests and S-T segment depression >3 mm without angina in the third test.

S-T segment elevation was observed in 2 patients (Cases 3 and 4) during 1 exercise test and in 1 patient (Case 5) during 2 tests. In 6 patients (Cases 1, 6, 8, 9, 11, and 12) all 3 exercise tests induced S-T segment depression. In 5 of these patients, S-T segment depression occurred at different work loads with a wide range of values of double product. One illustrative case is shown in Figure 1. In 1 patient (Case 8) exercise tolerance did not change substantially during the 3 tests; however S-T depression was more marked during the first than during the second exercise test although a higher value of double product was attained during the latter.

**Angiographic features:** No patient had akinetic or dyskinetic areas of the left ventricle. The average ejection fraction was 59 ± 7 and the average left ventricular end-diastolic pressure was 12.5 ± 5 mm Hg. Coronary

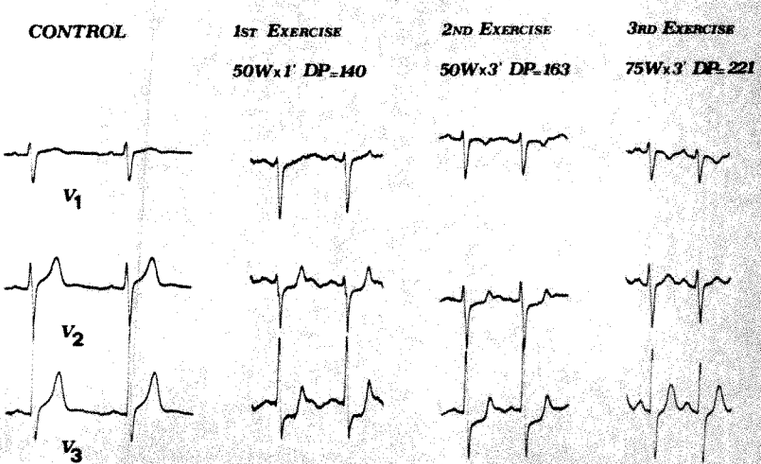

**FIGURE 1.** Case 11. Three exercise tests performed in the morning on different days yielded different results. The first and second tests induced chest pain and S-T segment depression, whereas the third test was negative despite a higher double product. DP = double product (mm Hg × beats/min × $10^{-2}$).

**TABLE III Great Cardiac Vein Flow During Exercise Tests Before and After Administration of Nifedipine**

| | Work Load | End-point | ECG Changes | Double Product (mm Hg beats/min $10^{-2}$) | GCVF (ml/min) |

| | | | ... | ... | ... |

Ang = angina; ECG = electrocardiographic; Exh = exhaustion; GCVF = great cardiac vein flow; ↓S-T = S-T segment depression; — = no electrocardiographic changes.

arteriography (Table II) showed normal coronary arteries in 2 patients. Seven patients had single-vessel disease with involvement of the left anterior descending artery in 5, of the right coronary artery in 1 and of the circumflex branch in 1.

Three patients had 2-vessel disease. During the procedure, 2 patients exhibited a spontaneous spasm of the right coronary artery and 1 of the left anterior descending artery. One patient had an ergonovine-induced spasm of the left anterior descending artery.

**Great cardiac vein flow measurements (Table III):** Both patients showed an increase in flow at peak exercise. After administration of nifedipine they tolerated heavier work loads than before and attained higher values of double product. Despite that, electrocardiographic signs of ischemia did not appear in 1 patient and occurred at far greater values of double product in the other. The increase in flow in the great cardiac vein at peak exercise was more marked after than before administration of nifedipine (Fig. 2).

## Discussion

**Variability of angina threshold during exercise:** Stable exertional angina is caused by increased myocardial oxygen consumption in the presence of fixed stenoses of the large coronary arteries. The concept that coronary lesions are fixed implies that myocardial ischemia occurs reproducibly at a given level of myocardial oxygen consumption. Epstein and Talbot[19] recently challenged this concept, because it does not explain several clinical characteristics often observed in patients with angina pectoris. For instance, "... it does not explain why angina threshold should vary markedly during different times of the day, different times of the week, or different seasons of the year."[19] This lack of reproducibility and predictability has been reported in classic descriptions of angina of effort.[20,21] Friedberg,[20] observing that some patients have only occasional seizures at intervals of days, weeks, or months, comments that "these intervals depend to some extent on avoidance of the factors which elicit the anginal attacks."

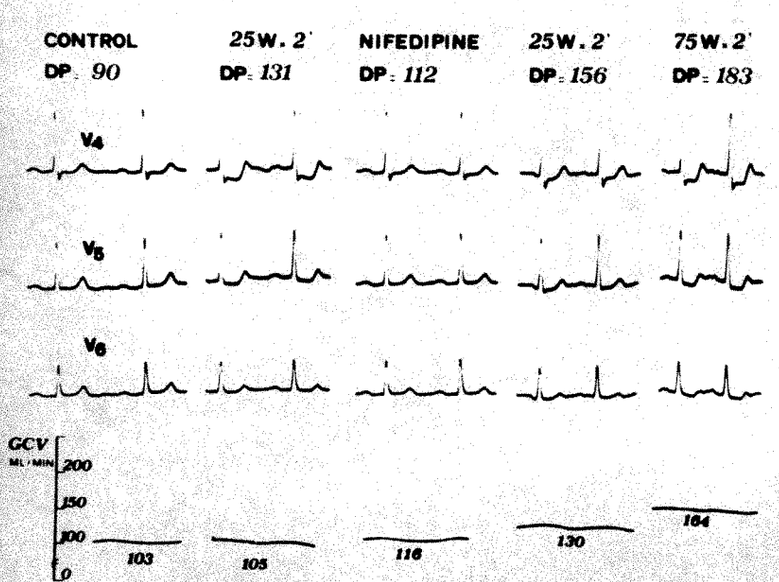

**FIGURE 2.** Case 12. In this patient with disease of an isolated left anterior descending artery, measurements of great cardiac vein flow were performed during exercise, before and after administration of nifedipine. After the drug, the patient tolerated a greater work load and attained a higher value of double product. This beneficial effect was achieved by an increase in great cardiac vein flow. DP = double product (mm Hg × beats/min × $10^{-2}$); GCVF = great cardiac vein flow measurements (ml/min).

SUSTAINED RELEASE

# Procan® SR

## (PROCAINAMIDE HYDROCHLORIDE TABLETS)

250-mg tablet / 500-mg scored tablet / 750-mg scored tablet

## Enhances the value of oral procainamide for selected cardiac dysrhythmias

With modern sustained-release Procan SR, short duration of effect no longer impedes the usefulness of procainamide for maintenance therapy. A standard medication now assumes greater importance, both in terms of convenience and patient compliance.

Administered half as often as conventional oral procainamide

Wide versatility in cardiac conditions

Can be used concomitantly with digoxin

Ideal maintenance therapy

If in the past you have substituted another medication for maintenance therapy because of compliance problems with conventional oral procainamide, now you can logically turn to the modern oral procainamide.

## Procan SR... the original sustained-release oral procainamide

**PARKE-DAVIS**

Morris Plains, New Jersey 07950

Please see next page for brief summary of prescribing information.

**Procan® SR**
**(procainamide hydrochloride tablets)**
**SUSTAINED RELEASE**

**Before prescribing, please see full prescribing information.**
**A Brief Summary follows.**

The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

**INDICATIONS AND USAGE:** Oral procainamide is indicated in the treatment of premature ventricular contractions and ventricular tachycardia, atrial fibrillation, and paroxysmal atrial tachycardia.

**CONTRAINDICATIONS:** It has been suggested that procainamide be contraindicated in patients with myasthenia gravis. Hypersensitivity to the drug is an absolute contraindication; in this connection, cross-sensitivity to procaine and related drugs must be borne in mind. Procainamide should not be administered to patients with complete atrioventricular heart block. Procainamide is also contraindicated in cases of second-degree and third-degree A-V block unless an electrical pacemaker is operative.

**PRECAUTIONS: General** —During administration of the drug, evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of an abnormal myocardium, procainamide may at times produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed. Adequate digitalization reduces, but does not abolish, this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. Correction of atrial fibrillation, with resultant forceful contractions of the atrium, may cause a dislodgement of mural thrombi and produce an embolic episode. However, it has been suggested that in a patient who is already discharging emboli, procainamide is more likely to stop than to aggravate the process.

Attempts to adjust the heart rate in a patient who has developed ventricular tachycardia during an occlusive coronary episode should be carried out with extreme caution. Caution is also required in marked disturbances of atrioventricular conduction such as A-V block, bundle branch block, or severe digitalis intoxication, where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation.

Because patients with severe organic heart disease and ventricular tachycardia may also have complete heart block, which is difficult to diagnose under these circumstances, this complication should always be kept in mind when treating ventricular arrhythmias with procainamide. If the ventricular rate is significantly slowed by procainamide without attainment of regular atrioventricular conduction, the drug should be stopped and the patient reevaluated since asystole may result under these circumstances.

In patients receiving normal dosage, but who have both liver and kidney disease, symptoms of overdosage (principally ventricular tachycardia and severe hypotension) may occur due to drug accumulation.

Instances of a syndrome resembling lupus erythematosus have been reported in connection with maintenance procainamide therapy. The mechanism of this syndrome is uncertain. Polyarthralgia, arthritis, and pleuritic pain are common symptoms; to a lesser extent, fever, myalgia, skin lesions, pleural effusion, and pericarditis may occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia have been reported which may be related to this syndrome.

**Laboratory Tests**—Patients receiving procainamide for extended periods of time, or in whom symptoms suggestive of a lupus-like reaction appear, should have antinuclear antibody titers measured at regular intervals. The drug should be discontinued if there is a rising titer (antinuclear antibody) or clinical symptoms of LE appear. The LE syndrome may be reversible upon discontinuation of the drug. If discontinuation of the drug does not cause remission of the symptoms, steroid therapy may be effective. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not controllable by other antiarrhythmic agents, steroid suppressive therapy may be used concomitantly with procainamide. It is recommended that tests for lupus erythematosus be carried out at regular intervals in patients receiving maintenance procainamide therapy.

Routine blood counts are advisable during maintenance procainamide therapy.

**ADVERSE REACTIONS:** Agranulocytosis has occasionally followed the repeated use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance procainamide therapy. The patient should be instructed to report any soreness of the mouth, throat, or gums, unexplained fever, or any symptoms of upper respiratory tract infection. If any of these should occur, and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately.

Hypersensitivity reactions, such as angioneurotic edema and maculopapular rash have also occurred.

A syndrome resembling lupus erythematosus has been reported (see PRECAUTIONS).

Hypotension following oral administration is rare.

Large oral doses of procainamide may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

Reactions consisting of fever and chills have also been reported, including a case with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses of the drug. Bitter taste, diarrhea, weakness, mental depression, giddiness, and psychosis with hallucinations have been reported. The possibility of such untoward effects should be borne in mind.

**DOSAGE AND ADMINISTRATION:** Procan SR (procainamide hydrochloride) tablets are a sustained-release product form. The duration of action of procainamide hydrochloride supplied in this sustained-release product form allows dosing at intervals of every six hours instead of the more frequent every-three-hour dosing interval required for standard preparations of oral procainamide hydrochloride. The convenient six-hour dosing schedule may encourage patient compliance.

**Ventricular tachycardia**—Treatment with standard procainamide hydrochloride is recommended until the tachycardia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows: An initial dose of 1 g of standard procainamide hydrochloride followed thereafter by a total daily dose of 50 mg/kg of body weight given at three hour intervals. The suggested oral dosage for premature ventricular contractions is 50 mg/kg of body weight daily given in divided doses at three-hour intervals.

The suggested maintenance dosage of Procan SR is 50 mg/kg of body weight daily given in divided doses at six-hour intervals.

Although the dosage for each patient must be determined on an individual basis, the following may be used as a guide for providing the total daily dosage: patients weighing less than 55 kg (120 lb), 0.5 g every six hours; patients weighing between 55 and 91 kg (120 and 200 lb), 0.75 g every six hours; and patients weighing over 91 kg (200 lb), 1 g every six hours.

**Atrial fibrillation and paroxysmal atrial tachycardia**—Treatment with standard procainamide hydrochloride is recommended until the arrhythmia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows. An initial dose of 1.25 g of standard procainamide hydrochloride may be followed in one hour by 0.75 g if there have been no electrocardiographic changes. Standard procainamide hydrochloride may then be given at a dose of 0.5 to 1 g every two hours until interruption of the arrhythmia or the tolerance limit is reached.

The suggested maintenance dosage for Procan SR is 1 g every six hours.

If procainamide therapy is continued for appreciable periods, electrocardiograms should be made occasionally to determine the need for the drug.

**HOW SUPPLIED:** Procan SR 250 mg (green, film-coated tablet, P-D 202) is available in bottles of 100 (N 0071-0202-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0202-40). Each sustained-release tablet contains 250 mg procainamide hydrochloride.

Procan SR 500 mg (yellow, scored, film-coated tablet, P-D 204) is available in bottles of 100 (N 0071-0204-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0204-40). Each sustained-release tablet contains 500 mg procainamide hydrochloride.

Procan SR 750 mg (orange, scored, film-coated tablet, P-D 205) is available in bottles of 100 (N 0071-0205-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0205-40). Each sustained-release tablet contains 750 mg procainamide hydrochloride.

**Storage—Protect from moisture. Store bottles below 86° F (30° C). Store unit-dose packages at controlled room temperature, 59°-86° F (15°-30° C).**

# Getting the Manuscript Accepted: Think Like a Lawyer and Cover the Flanks

A manuscript might be viewed as a legal brief in which an author presents logical arguments supporting the contention that he has created and proven a new concept. Reviewers, in a way, are like defense lawyers who attempt to find a flaw in the author's contention. Finding such flaws often casts doubt on other claims of the author or claimant. Indeed, the finding by reviewers or the Editor of *omissions of mention* can be a major stumbling block preventing the acceptance of a manuscript.

A manuscript's quality may be compared to the game of tic-tac-toe, in which 2 players, in turn, fill in 9 compartments, 1 at a time, with X's and O's. The *best paper* fills in all the blocks—covers all the bases—and in addition lines up 3 X's in a row (see the figure below), signifying focus and clarity. A row of zeros indicates that the manuscript provides an essentially negative observation. A manuscript also can have all the blocks filled in but no symbols lined up in a row, indicating a lack of clarity and focus. The *worst paper* fails to fill in 1 or more compartments with either symbol (omissions of mention) and none line up in a row, an indication that the author has failed to mention all the points necessary to prove his case and to focus the points properly.

# In Hypertension*...When You Need to Conserve $K^+$

# Every Step of the Way

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

†Step 1 usually consists of an initial phase (a diuretic alone), a titration phase (dosage adjustment and/or addition of a $K^+$ supplement or $K^+$-sparing agent), and a maintenance phase (a diuretic alone or in combination with a $K^+$ supplement or $K^+$-sparing agent).

Serum $K^+$ and BUN should be checked periodically (see Warnings).

**Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary.**

* **WARNING**
This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

**Contraindications:** Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

**Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired.** If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum $K^+$ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict $K^+$ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

**Precautions:** Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have been reported. Thiazides have also been shown to increase the paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, 'Dyazide' should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on 'Dyazide' when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with 'Dyazide'. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. 'Dyazide' interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with 'Dyazide', but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and 'Dyazide' should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. 'Dyazide' should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

**Adverse Reactions:** Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances; postural hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on 'Dyazide', although a causal relationship has not been established.

**Supplied: Bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.**

## State of the Heart A-V Sequential Pacing.

Introducing the most flexible A-V Sequential Pacemaker.

**Small.**

Physiologically sized and shaped for maximum patient comfort. Byrel-SX™ weighs just 52 grams.

**Smart.**

The most programmable A-V sequential pacemaker. Byrel-SX™ is a non-committed system, and features Ventricular Safety Pacing to provide:

- Programmable A-V Intervals
- Ventricular inhibition

**Friendly.**

Byrel™ brand pacemakers have long been known for their dependability, reliability, ease of programming, and ease of follow-up.

These are Medtronic differences physicians recognize and need.

The new Byrel-SX™, leading the way in A-V Sequential pacing. For further information call toll free 1-800-328-2518.

## Byrel-SX Model 5993-SX Programmable Parameters

| | DVI | VVI |
|---|---|---|
| Rate | 40-120 bpm | 40-130 bpm |
| A-V Internal | 25-250 ms | NA |
| Atrial Pulse Width | 0.05, 0.1, 0.2...1.5 ms | NA |
| Ventricular Pulse Width | 0.05, 0.1, 0.2...1.5 ms | 0.05, 0.1, 0.2...1.5 ms |
| Ventricular Sensitivity | 2.5, 5.0 mv Asynchronous | 2.5, 5.0 mv Asynchronous |

**Power Source Depletion Characteristics**

**Initial Stage**

| | |
|---|---|
| Mode | as programmed |
| Voltage | 2.2 V |
| Magnet rate | 75 bpm |

**Secondary Stage**

| | |
|---|---|
| Mode | VVI at 65 bpm |
| Voltage | 2.0 V |

**INTENDED USE**

The Model 5993-SX universal A-V pulse generator has a wide range of application in patients requiring permanent cardiac pacing or to protect against arrhythmias related to the sequence of cardiac impulse propagation.

In the A-V sequential (DVI) mode, the Model 5993-SX has application in the following:

Sick Sinus Syndrome (sinus brady-cardia, sinus arrest, S-A block, and the brady-tachy syndrome).
A-V nodal reentrant tachycardias. (Short A-V interval settings may be useful in controlling reentrant tachy-cardias.)
Atrial and ventricular ectopic arrhythmias.

At any time, the Model 5993-SX can be programmed to the VVI mode in which case the device functions as a ventricular inhibited pulse generator. This mode is intended primarily as a backup mode in situations where it is necessary to disable the atrial circuitry (e.g., atrial lead malfunction).

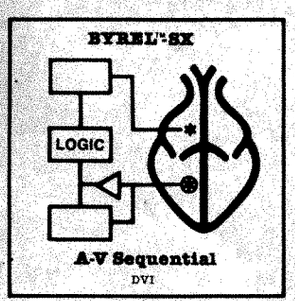
NOTE: The Medtronic® Model 5993-SX A-V pulse generator is under clinical investigation. The procedures for using this pulse generator, as well as its safety and efficacy, will be evaluated during this investigational study according to the Clinical Investigation Protocol. Therefore, the "Intended Use" section is based on Medtronic's experience with other physiologic pulse generators. No claims for safety and efficacy can be made for the Model 5993-SX pulse generator during its clinical investigation. Patients should be advised that the Model 5993-SX generator is under clinical investigation.

**CONTRAINDICATIONS**

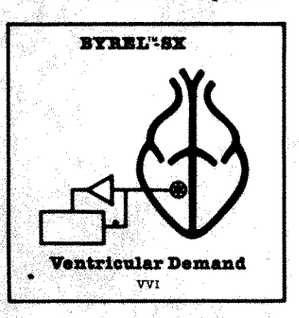
There are no known contraindications to the use of pacing as a therapeutic modality for control of heart rate. The patient's age and medical condition, however, may dictate the particular pacing system, mode of operation, and implantation procedure used by the physician. In the DVI mode, atrial pacing is ineffective in the presence of chronic atrial fibrillation of flutter.

**WARNINGS**

Diathermy should not be used on patients with pacemakers because of possible heating effects in the pulse generator and at the implant site. Electrosurgical units should never be used in the vicinity of unipolar pulse generators because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator.



Positioning a magnet or the programmer over the pulse generator makes it subject to programming. Do not use electrocautery, diathermy, or any other source of electromagnetic interference in the vicinity of the patient once a magnet or programmer has been positioned over the pulse generator.



**PRECAUTIONS**

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

**SIDE EFFECTS**

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

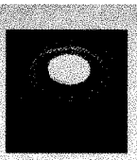
# Two added strengths for ease of titration.

## The new 5 cm² size.

Nitro-Dur™ (nitroglycerin) is the only transdermal nitroglycerin with four dosage strengths—5, 10, 15 and 20 cm² (approximately 2.5 mg, 5 mg, 7.5 mg and 10 mg released in 24 hours), permitting titration in increments of 5 cm². This gives Nitro-Dur greater dosage flexibility than any other form of transdermal nitroglycerin.

Nitro-Dur also has a sophisticated product design which includes a wide, microporous adhesive strip. The strip insures firm matrix-to-skin contact and helps keep the system sealed and in place.



Greater dosage flexibility and better adhesion. Two reasons why Nitro-Dur is the most widely prescribed transdermal nitroglycerin system.

**Nitro-Dur™**
(nitroglycerin)
Transdermal Infusion System

**The most widely prescribed transdermal nitroglycerin system.**

Please see next page for a summary of prescribing information.

# Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

## The most widely prescribed transdermal nitroglycerin system.

**DESCRIPTION:** The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing precise dosing levels of nitroglycerin. Nitro-Dur has a rated release *in vivo* of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

**CLINICAL PHARMACOLOGY:** When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies,[1] transdermal absorption of nitroglycerin from the gel-like matrix achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Therapeutic effect is achieved within 30 minutes after application of the unit, and persists about 30 minutes after removal of the unit.

**INDICATIONS AND USAGE:** Prevention and treatment of angina pectoris due to coronary artery disease.

**CONTRAINDICATIONS:** Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

**WARNINGS:** The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

**PRECAUTIONS:** Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

**ADVERSE REACTIONS:** Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

**HOW SUPPLIED:** Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28.

**CAUTION:** Federal law prohibits dispensing without a prescription.

**PATIENT INSTRUCTIONS FOR APPLICATION:** Patient instructions are furnished with each unit dose package.

*Laragh's eagerly awaited new book on the silent killer*

# TOPICS IN HYPERTENSION

Edited by
**John H. Laragh, MD**
*Master Professor of Medicine*
*Director, The Cardiovascular Center Chief, Cardiology Division The New York Hospital-Cornell Medical Center*

**644 pages. 36 chapters by 85 internationally known specialists. Illustrated. Comprehensively indexed. $49.00. Available on 30-day approval.**

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice...and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

This book is conveniently organized for effective consultation and reading:

- **Section 1** considers recently maturing biochemical and pathophysiologic aspects of the problem.
- **Section 2** deals with new physiologic approaches to diagnosis.
- **Section 3** discusses new perceptions of the clinical and prognostic aspects of hypertension.
- **Section 4** considers in detail the more recently introduced modes of therapy. These new agents presage the beginning of a new era of more selective and specific therapy for increasing numbers of patients.

**YORKE MEDICAL BOOKS** AJCA3
Box C-757, Brooklyn, New York 11205

Send me, on approval, _____ copies of Laragh's TOPICS IN HYPERTENSION at $49.00. I will consult and read this new manual for 30 days, then remit only if I consider it a necessary addition to my library. Otherwise I will return it without further obligation.

NUMBER 1

## CONTENTS

### CORONARY HEART DISEASE

1 **Exercise 2-Dimensional Echocardiography. Quantitation of Left Ventricular Performance in Patients With Severe Angina Pectoris**

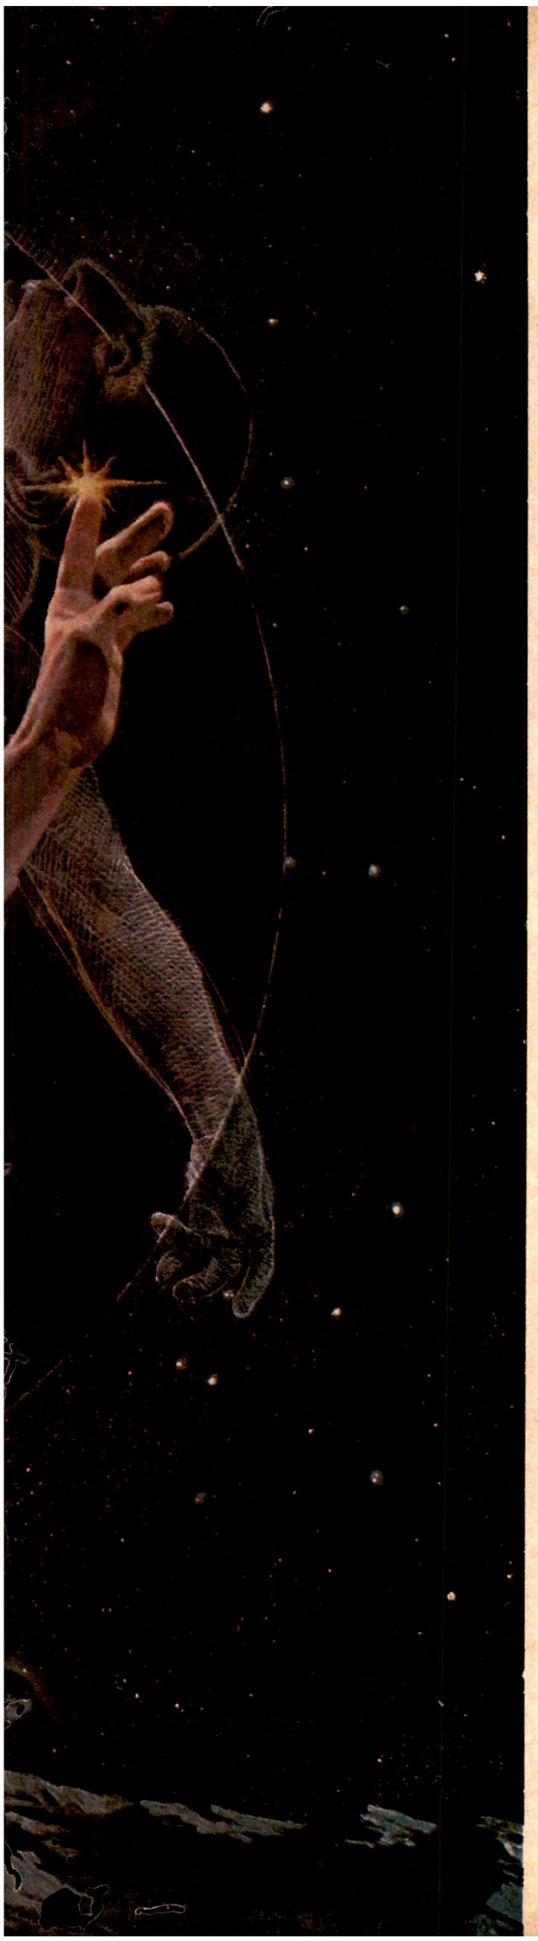
MICHAEL H. CRAWFORD, K. WRAY AMON, and WILLIAM S. VANCE

The feasibility and reproducibility of exercise biapical 2-dimensional echocardiography for quantitating left ventricular performance was assessed in 25 patients with severe coronary artery disease and in 10 normal subjects. In 18 of the 25 patients (72%) adequate echoes were recorded during upright bicycle exercise. Ejection fraction increased in the normal subjects during exercise but not in the patients. After nitroglycerin administration 7 patients (39%) showed marked increases in ejection fraction during exercise. Wall motion score worsened during exercise in the patients before nitroglycerin, but was significantly improved after nitroglycerin administration. Therefore, quantitation of left ventricular performance during exercise by biapical 2-dimensional echocardiography can be accomplished in a high proportion of patients with coronary artery disease.

7 **Importance of Complete Revascularization in Performance of the Coronary Bypass Operation**

ELLIS L. JONES, JOE M. CARVER, ROBERT P. GUYTON, DAVID K. BONE, CHARLES R. HATCHER, Jr., and NORMAN RIECHWALD

Data bank records of 1,238 patients with triple vessel disease and coronary bypass surgery were retrospectively divided into 2 groups depending on whether complete or incomplete revascularization had been accomplished. Patients with complete revascularization had a higher incidence of normal preoperative electrocardiograms than did patients with incomplete revascularization (23% versus 14%, respectively). There was no significant difference between the completely and incompletely revascularized patients with regard to postoperative inotropic requirements (8% and 7%), ventricular arrhythmias (1.8% and 1%), necessity for intraaortic balloon pumping (1.6% and 1.5%), hospital mortality (1.2% and 2.8%), or myocardial infarction (4.3% and 4.8%). Survival at 5 years was significantly greater in patients with complete (88.5%) than in those with incomplete revascularization (83.5%). Reemployment was more common in patients with complete (52%) than in those with incomplete revascularization (40%) and more patients were angina-free. Long-term survival appeared to be mediated primarily through improved revascularization rather than differences in left ventricular function.



13 **Antianginal Efficacy and Improved Exercise Performance With Timolol. Twice-Daily Beta Blockade in Ischemic Heart Disease**

FRED J. HARRIS, REGINALD I. LOW, LINDA PALMER, EZRA A. AMSTERDAM, and DEAN T. MASON

Antianginal efficacy and improved exercise performance of timolol, a new beta blocker, was assessed in 23 patients with chronic stable angina pectoris in an 11-week, double-blind, placebo-controlled study. Twenty-two of 23 subjects completed the open-label phase (weeks 0 to 6) while receiving 10 to 30 mg of timolol twice daily to optimize exercise capacity. Weekly anginal episodes and nitroglycerin consumption decreased on timolol compared with placebo. Resting heart rate (HR), systolic blood pressure (SBP), peak exercise HR, peak exercise SPB, and peak exercise double product were significantly ($p < 0.05$) reduced 12 to 13 hours after timolol compared with placebo. Exercise duration was prolonged and the time of onset of 1 mm S-T segment depression was delayed in 15 patients. During the double-blind phase (weeks 7 to 10), resting HR, peak exercise HR, and peak exercise double product were significantly attenuated in 8 timolol patients although unchanged in 11 placebo subjects. Exercise duration was again prolonged at week 8 in timolol subjects compared with initial placebo, but not at week 10. Placebo patients demonstrated no difference at week 8 or 10 in exercise performance compared with initial placebo treatment. Timolol twice daily, therefore, is potentially useful in some patients with angina pectoris. Others may, however, require a more frequent dosing interval for optimal angina control and maximal improvement in exercise capacity.

# THE ALPHA UNIVERSE

## ...is the Catapres® universe of central alpha control* for all kinds of hypertensives

**No contraindications** to Catapres — you can prescribe it for:**

- **Asthmatic hypertensives**
  Does not act directly on beta$_2$ receptors of the lungs (blocking these receptors induces bronchospasm).
- **Diabetic hypertensives**
  Lowers blood pressure without impairing oral antidiabetic effectiveness.
- **Hypertensives with renal insufficiency**
  Lowers blood pressure without long-term reduction of cardiac output. (Does not reduce renal perfusion or GFR.)
- **Hypertensives with congestive heart failure**
  Does not depress myocardial contractility.
- **Stress-induced hypertension**
  Inhibits sympathetic nervous activity centrally and does not elevate plasma catecholamines.
- **Elderly hypertensives**
  Recommended in isolated systolic hypertension in the elderly.[1]

*Central alpha-adrenergic stimulation decreases sympathetic outflow from the brain, as shown in animal studies.

**Like any antihypertensive, use with caution in severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

1. Statement on Hypertension in the Elderly, Revised April, 1980. Approved by the National High Blood Pressure Education Program Coordinating Committee.

Tablets of 0.1, 0.2, 0.3 mg

# Catapres®

## (clonidine HCl)

## Hypertension

Please see brief summary of PI for warnings, precautions, and adverse reactions.

# THE ALPHA UNIVERSE

Tablets of 0.1, 0.2, 0.3 mg

**Catapres®**
(clonidine HCl)
**Hypertension**

## Catapres®

**(clonidine hydrochloride)**
**Tablets of 0.1, 0.2, 0.3 mg**

**Indication:** The drug is indicated in the treatment of hypertension. As an antihypertensive drug, Catapres (clonidine hydrochloride) is mild to moderate in potency. It may be employed in a general treatment program with a diuretic and/or other antihypertensive agents as needed for proper patient response.

**Warnings:** Tolerance may develop in some patients necessitating a reevaluation of therapy.
*Usage in Pregnancy:* In view of embryotoxic findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefits outweigh the potential risk to mother and fetus.
*Usage in Children:* No clinical experience is available with the use of Catapres (clonidine hydrochloride) in children.

**Precautions:** When discontinuing Catapres (clonidine hydrochloride), reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of clonidine hydrochloride therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other agent lowering blood pressure, clonidine hydrochloride should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Catapres (clonidine hydrochloride) should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmologic findings have been recorded with Catapres (clonidine hydrochloride), in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

**Adverse Reactions:** The most common reactions are dry mouth, drowsiness and sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy. The following reactions have been associated with the drug, some of them rarely. (In some instances an exact causal relationship has not been established.) These include: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one report of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone and papaverine hydrochloride. Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase; congestive heart failure, Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and mental depression. Also rash, angioneurotic edema, hives, urticaria, thinning of the hair, pruritus not associated with a rash, impotence, urinary retention, increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as Wenckebach period or ventricular trigeminy.

**Overdosage:** Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres (clonidine hydrochloride) by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals usually abolishes all effects of Catapres (clonidine hydrochloride) overdosage.

**How Supplied:** Catapres, brand of clonidine hydrochloride, is available as 0.1 mg (tan) and 0.2 mg (orange) oval, single-scored tablets in bottles of 100 and 1000 and unit dose package of 100.. Also available as 0.3 mg (peach) oval, single-scored tablets in bottles of 100.

For complete details, please see full prescribing information.
Under license from Boehringer Ingelheim International GmbH

*The Alpha Universe*, a painting by Arthur Lidov, commissioned by Boehringer Ingelheim Ltd.

Lidov's work, the second in a series on central alpha action, interprets the Alpha Universe on many levels...the universe of patients who can benefit from the central alpha control of Catapres...the special world of patient/clinician interaction... the internal universe within each patient that determines or modifies his therapy...and the universe of medicine itself. Lidov is a painter whose art invites us to share his own fascination with the creativity inherent in science.

If you like this painting, we would be pleased to send you a handsome reproduction suitable for framing...with our compliments.

# Picker International is the source for cardiography systems.

# To you, this is important.

Having a single source dedicated to meeting all of your cardiography equipment needs can save time in your decision making process.

And, a single source for your service and supply needs can save you time after your purchase, as well.

This three channel ECG with its versatile interactive memory is just one of the exciting new products available from our Cambridge Medical Instruments Group. Others include automatic and manual single channel ECG's; conventional and computer assisted stress test systems; ambulatory and telemetry monitoring systems; and the first truly portable ultrasound system.

We'd like to tell you more about our cardiography systems. Please write Picker International, Inc., 73 Spring St., Ossining, NY 10562; Telephone 914/941-8100 or Telex 137337.

**PICKER INTERNATIONAL**

43 **Radionuclide Analysis of Peak Filling Rate, Filling Fraction, and Time to Peak Filling Rate. Response to Supine Bicycle Exercise in Normal Subjects and Patients With Coronary Disease**

G. B. JOHN MANCINI, ROBERT A. SLUTSKY, SHARON L. NORRIS, VALMIK BHARGAVA, WILLIAM L. ASHBURN, and CHARLES B. HIGGINS

Using gated equilibrium radionuclide angiography, parameters of diastolic filling were analyzed at rest and during exercise in normal subjects and patients with coronary disease with both normal and reduced resting ejection fractions. Indexes analyzed were peak filling rate and the filling fraction during the first third of diastole. At rest the peak filling rate and filling fraction were significantly lower in coronary patients than in normal subjects, and these differences persisted at peak exercise. The time from end-systole to peak filling was also analyzed and found to be longer at rest in patients with a normal resting ejection fraction than in normal subjects. This also remained true when the time to peak filling was normalized by the R-R interval. Although the exercise time to peak filling was longer in coronary patients than in normal subjects, these differences were not apparent when the interval was normalized by the R-R interval. It is concluded that abnormalities in peak filling rate and filling fraction exist in patients with coronary disease both at rest and during exercise; however, large overlaps exist between normal subjects and such patients. Furthermore, caution is advised in the comparison of timing of events during diastole because apparent group differences may be partly related to rest or exercise heart rate.

52 **Determinants of Variable Exercise Performance Among Patients With Severe Left Ventricular Dysfunction**

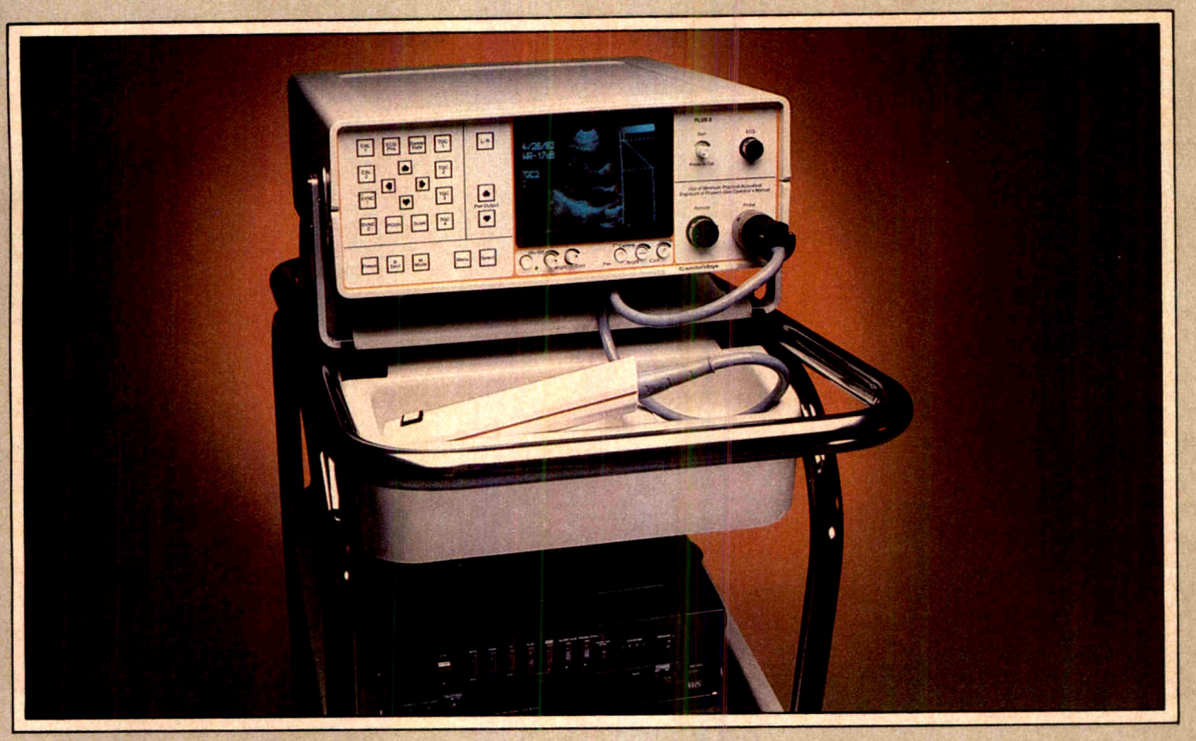
MICHAEL B. HIGGINBOTHAM, KENNETH G. MORRIS, ERIC H. CONN, R. EDWARD COLEMAN, and FREDERICK R. COBB

Cardiovascular responses were assessed in 17 patients with reduced left ventricular function and widely varying exercise tolerance. Maximal aerobic capacity was expressed as multiples of the resting oxygen consumption ($\dot{V}O_2$), or Mets. Radionuclide ejection fraction (EF), end-diastolic counts (EDC), stroke counts, and count output (CO) were measured at rest and during exercise; arteriovenous oxygen difference was derived from $\dot{V}O_2$ and CO. Exercise performance was reduced in patients compared with normal controls, and was limited by a poor CO response, since arteriovenous oxygen difference increased normally. The reduced CO response in patients resulted from failure of EF to increase or a diminished chronotropic reserve, or both. The resting EF in patients ranged from 0.09 to 0.36, but was unrelated to the variable Mets achieved in the group. Analysis of exercise responses identified changes in heart rate, CO, and arteriovenous oxygen difference, but not EF or stroke counts, as important determinants of Mets. The variable exercise performance among patients with severe left ventricular dysfunction was determined predominantly by variable heart rate and arteriovenous oxygen difference response rather than by rest or exercise indexes of left ventricular function.

61 **Determinants of Ventricular Tachycardia in Patients With Coronary Artery Disease and Ventricular Aneurysm. Clinical, Hemodynamic, and Angiographic Factors**

MARC COHEN, ISAAC WEINER, AUGUSTO PICHARD, JAMES HOLT, HARRY SMITH, Jr., and RICHARD GORLIN

In order to determine which factors are associated with the development of ventricular tachycardia in patients with ventricular aneurysms, the records of 154 patients with coronary artery disease and ventricular aneurysms were reviewed. Eighty-five of these patients had Holter monitoring or continuous electrocardiographic monitoring within 6 months of catheterization. Nineteen patients had ventricular tachycardia and 66 did not. There were no significant differences in the 2 groups with respect to age, time from first myocardial infarction to catheterization, congestive heart failure, or ejection fraction. Patients with ventricular tachycardia had significantly larger aneurysms and a much higher prevalence of septal akinesia.



65 **Relation of Exercise to the Recurrence Rate of Myocardial Infarction in Man. Ontario Exercise-Heart Collaborative Study**

PETER A. RECHNITZER, DAVID A. CUNNINGHAM, GEORGE M. ANDREW, CAROL W. BUCK, NORMAN L. JONES, TERENCE KAVANAGH, NEIL B. OLDRIDGE, JOHN O. PARKER, ROY J. SHEPHARD, JOHN R. SUTTON, and ALLAN P. DONNER

The Ontario Exercise-Heart Collaborative Study was a randomized clinical trial for the prevention of recurrent infarction in men under 56 years of age. Three hundred seventy-nine men were assigned to a high intensity exercise program designed to produce a significant training effect, and 354 men were allocated to a low intensity exercise program structured to produce a minimal training effect. The trial was stratified for blue collar occupation,

# Picker International. The Source for Echocardiography.

## Introducing Plus 2, A Revolutionary Portable Ultrasound System Offering High Quality M-mode And 2-D Imaging.

Now conduct echocardiography studies in your office, clinic, or CCU. Plus 2 is the only dual purpose echo system that's so portable it can go wherever you go.

Picker International has combined the latest microprocessor and ultrasound technology in a lightweight unit that is dramatically smaller and more versatile than competitive units. In clinical situations you can have this powerful diagnostic tool at bedside for your critically ill patients. And, you can easily take Plus 2 on the road with you for examination of patients in localities where equipment is not available.

Best of all, Picker International's Plus 2 portable ultrasound system is less than half the cost of other systems offering comparable diagnostic capabilities. And Plus 2 is backed by Picker International Regional Service Centers worldwide, giving you prompt, dependable service.

So come to the Source for portability in ultrasound systems. Call your Cambridge representative today. Or contact the Cambridge Division, Picker International, Inc., 73 Spring Street, Ossining, NY 10562. Tel: 914/941-8100.

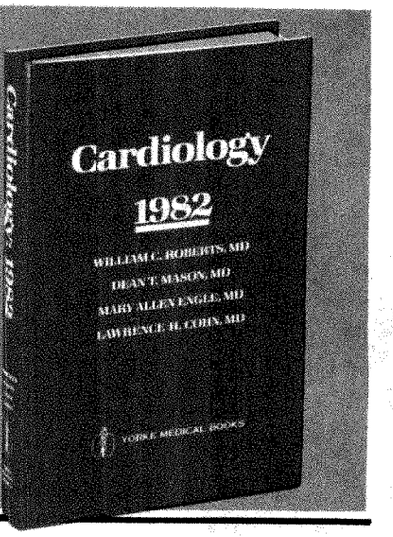
# CARDIOLOGY 1982



## The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

*written by:*

- **William C. Roberts, M.D.**
  *Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.*
- **Dean T. Mason, M.D.**
  *Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California*
- **Mary Allen Engle, M.D.**
  *Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York*
- **Lawrence H. Cohn, M.D.**
  *Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston*

**ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066**

## What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

## CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

**CARDIOLOGY: 1982** provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well-established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and original tables condenses valuable information into instantly understandable knowledge.

### *Reviews of the first edition*

***"...recommend...to any reader interested in the literature of cardiology."***
Irwin R. Callen, M.D.
JAMA, November, 1981

***"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."***
Philip Reichert, M.D.
New York State Journal of Medicine, September, 1981

***"This is an excellent book, very well organized and written...should be on the shelf of the library, cardiologist, and internist."***
COL. Robert B. Franklin, MC, USA
Military Medicine, November, 1981

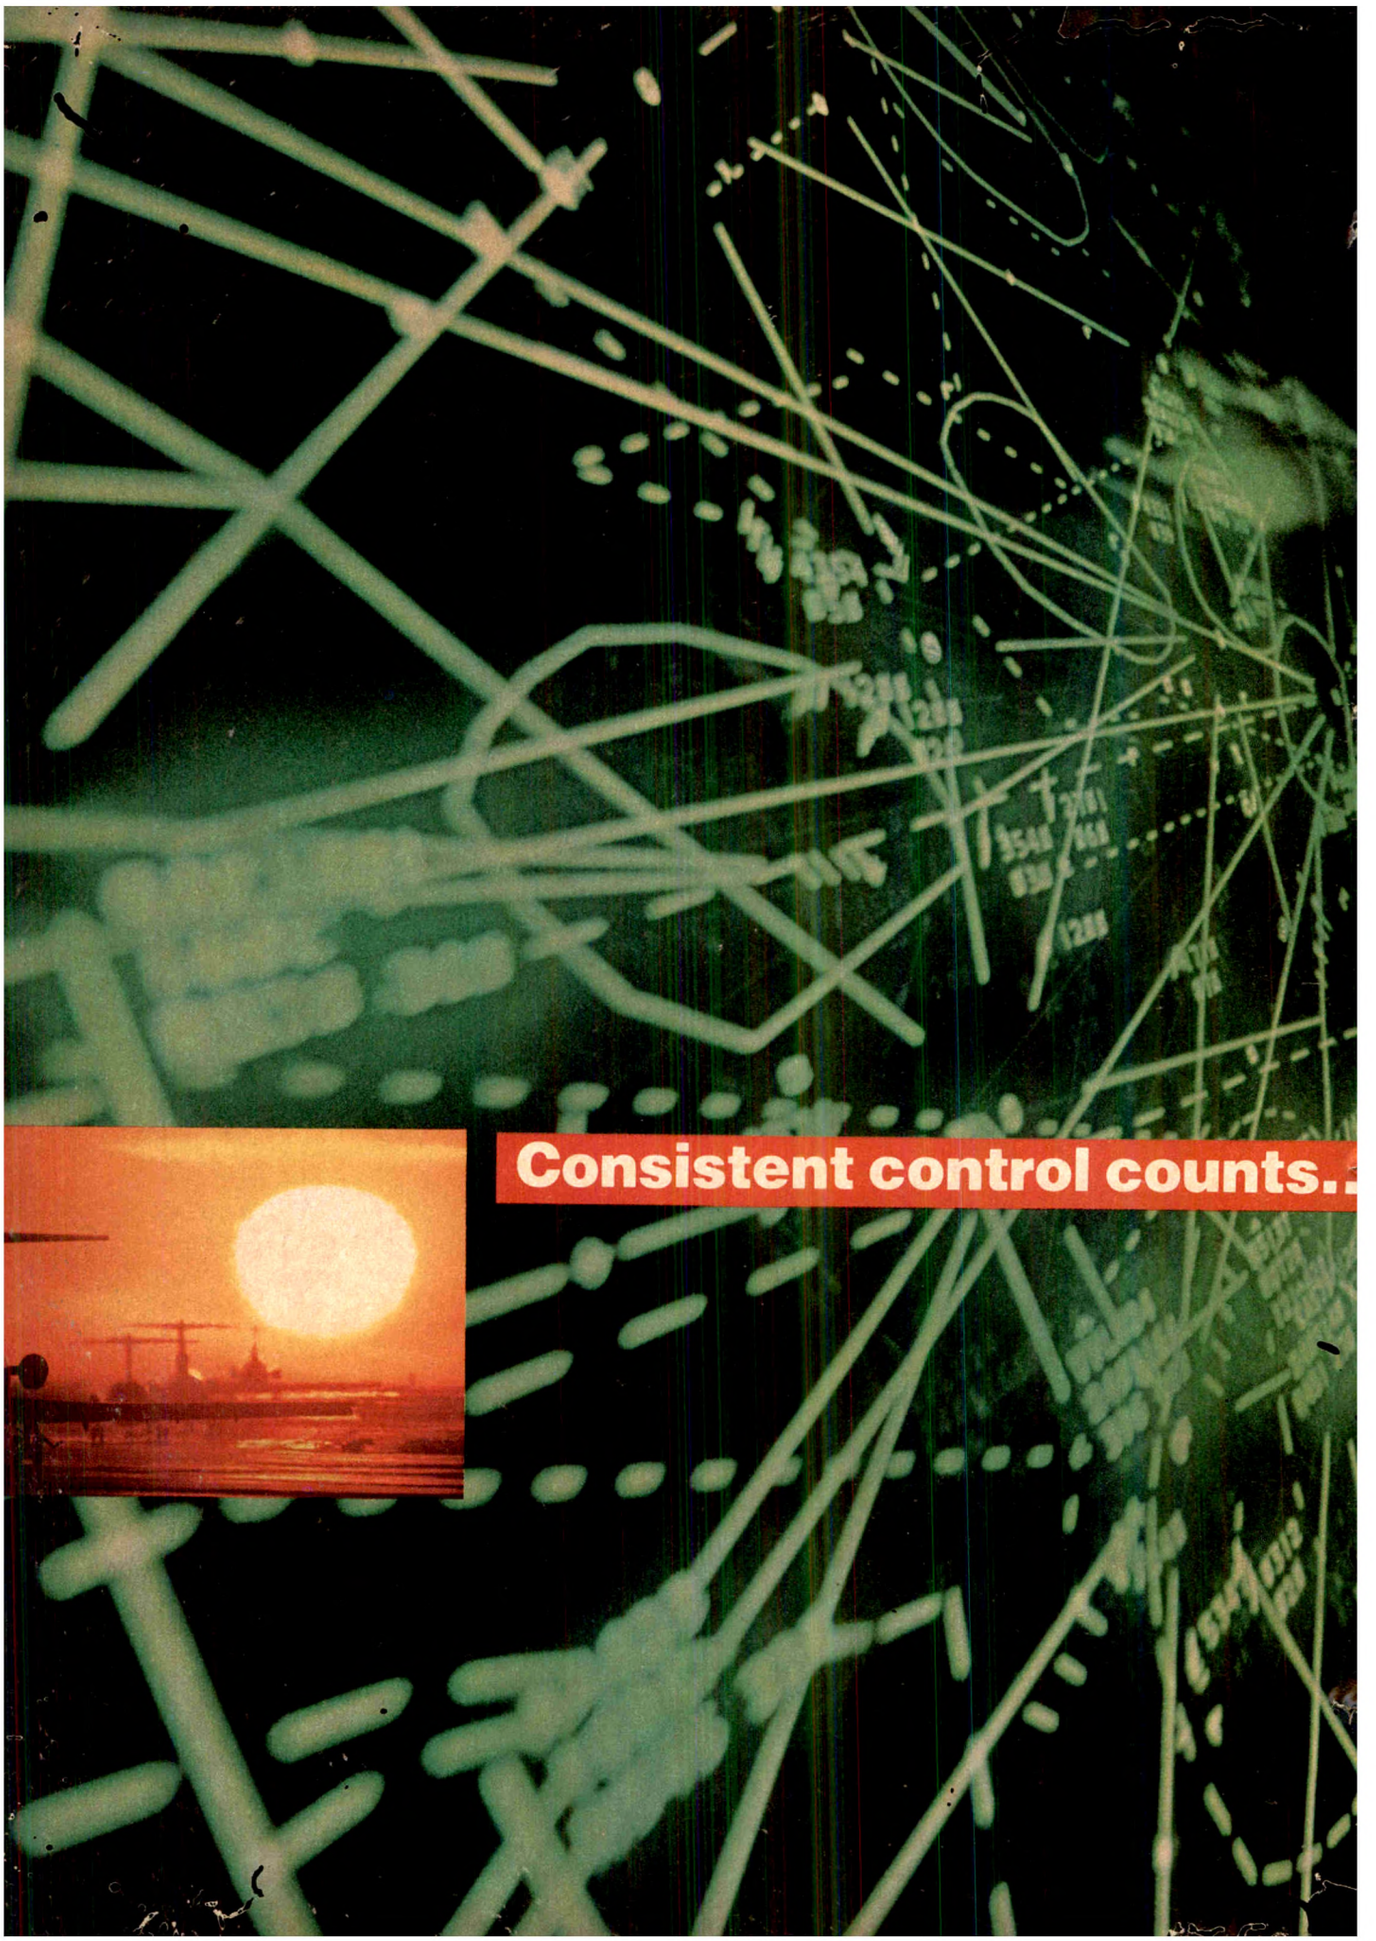
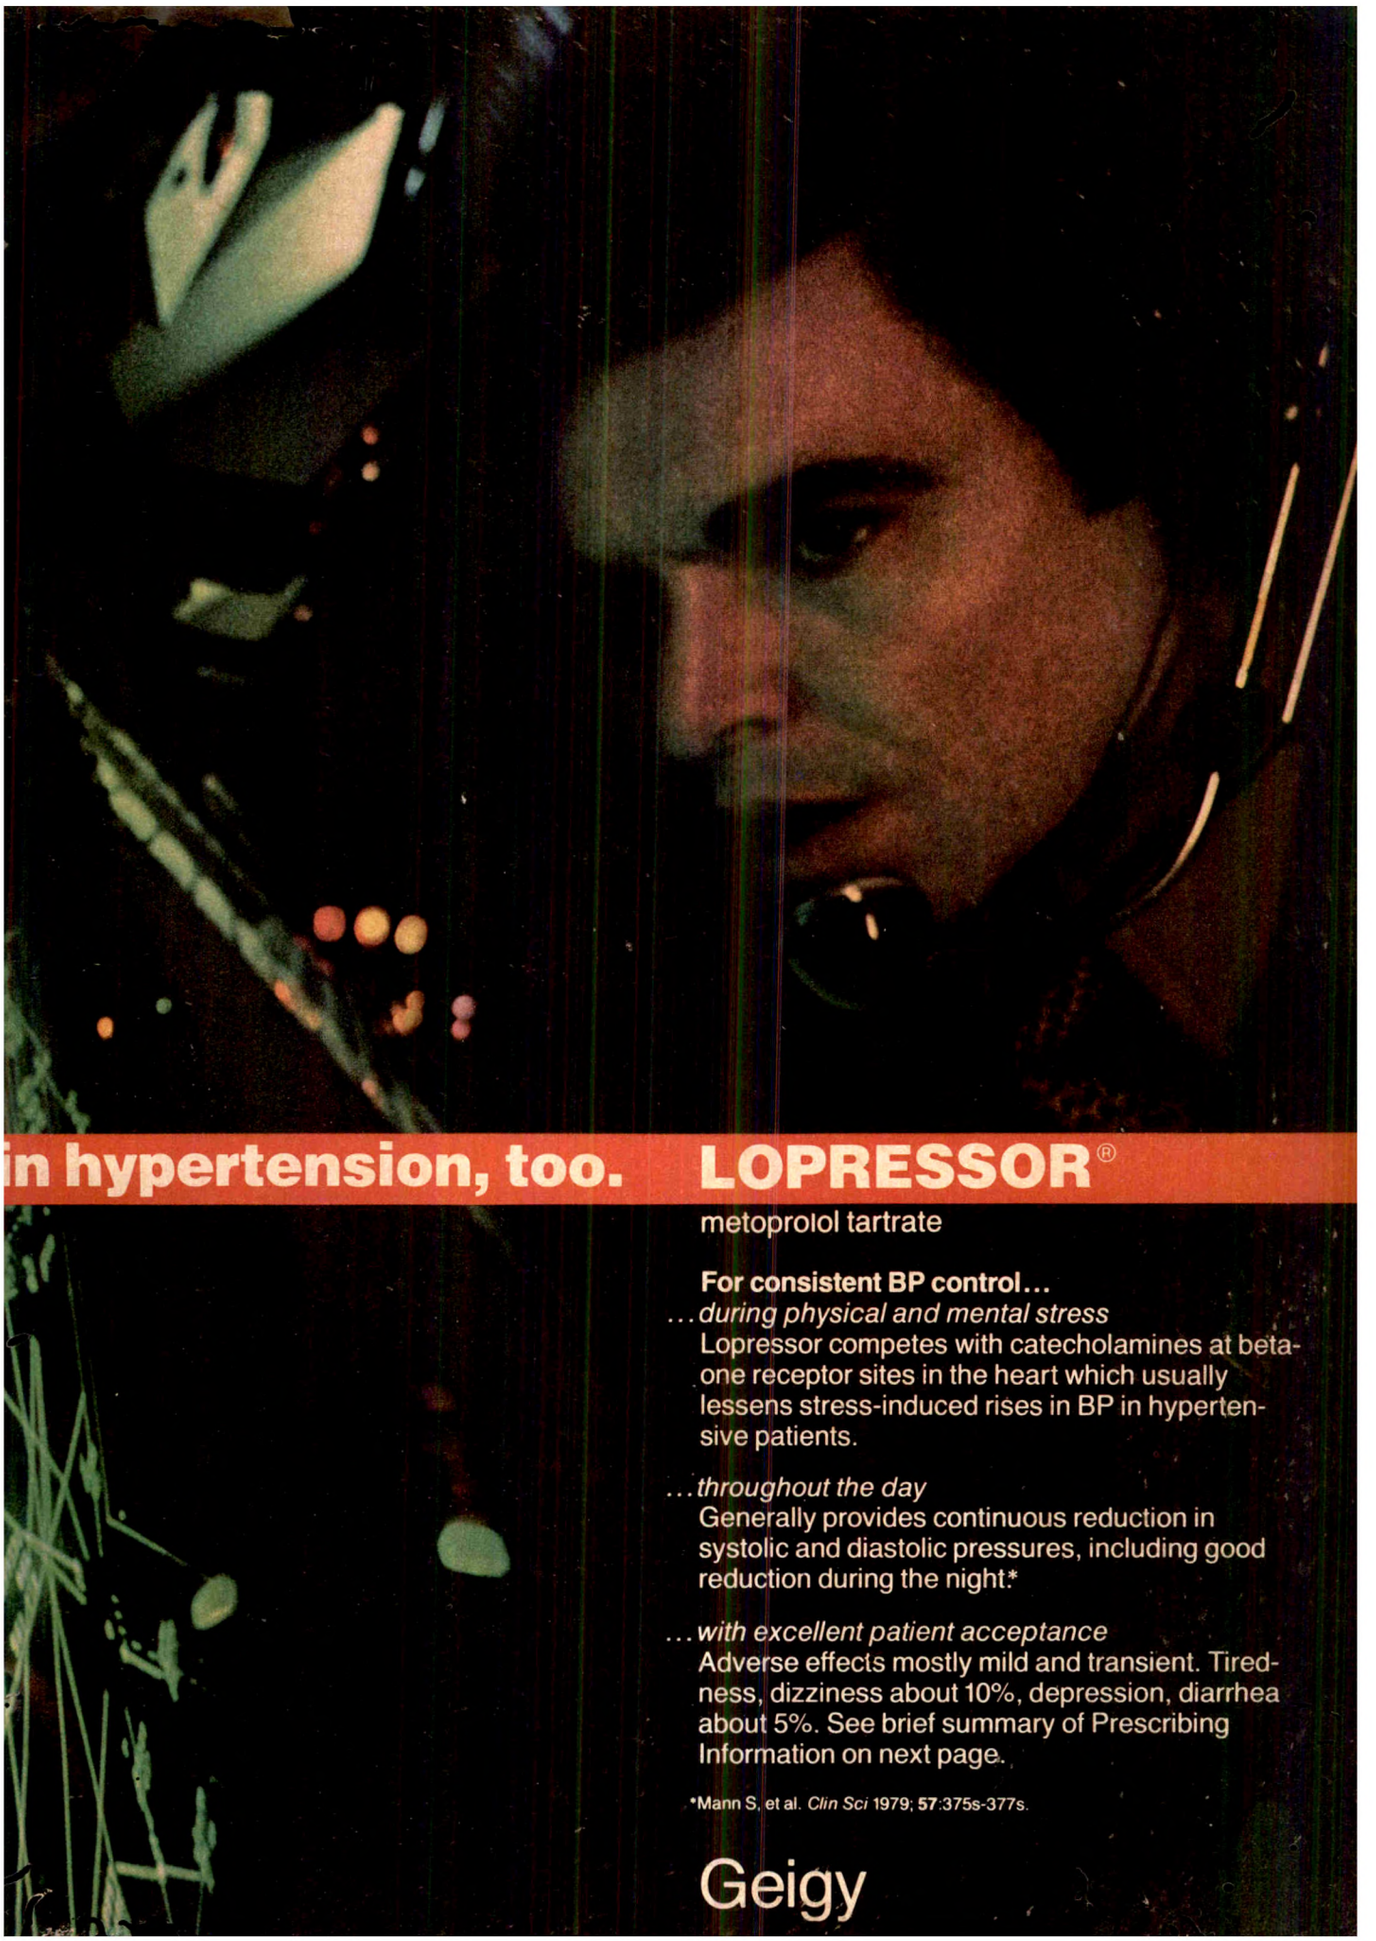
# Picker International. The Source for Stress Test Systems.

## Observer™...an Unbeatable Combination of Value and Capability



**Capability.** This new computerized System contains everything you need to perform smooth, error-free stress tests. Observer™ offers three, twelve, and fifteen lead ECG write-outs, signal averaging to suppress muscle artifact and noise, automatic sequencing of treadmill and recorder, and more. During the test, ST level and slope, heart rate and R-wave amplitude are continuously computed and displayed. These measurements are accumulated and presented as trend graphs on the final report. Cursor controls enable the physician to set or reposition the ST measurement point without having to interrupt the test.



**Value.** Observer™ has been engineered exclusively for the health care professional. Its versatile, modular design allows us to offer you a fully capable system in a configuration that's especially suited to your particular laboratory and budgetary requirements.

So, come to the Source for Stress Test Systems. And ask your Cambridge representative about Observer™ today. Or write or phone us direct at: Picker International, Inc., Cambridge Medical Instruments Division, 73 Spring Street, Ossining, NY 10562. Tel: 914/941-8100.

PHYSICIANS LIBRARY

**PICKER INTERNATIONAL**

Consistent control counts..

**in hypertension, too.** **LOPRESSOR®**

metoprolol tartrate

**For consistent BP control…**

…*during physical and mental stress*
Lopressor competes with catecholamines at beta-one receptor sites in the heart which usually lessens stress-induced rises in BP in hypertensive patients.

…*throughout the day*
Generally provides continuous reduction in systolic and diastolic pressures, including good reduction during the night.*

…*with excellent patient acceptance*
Adverse effects mostly mild and transient. Tiredness, dizziness about 10%, depression, diarrhea about 5%. See brief summary of Prescribing Information on next page.

*Mann S, et al. *Clin Sci* 1979; **57**:375s-377s.

Geigy

# Lopressor®
**metoprolol tartrate**

An antihypertensive beta-blocking agent

Tablets of 50 mg
Tablets of 100 mg

*Brief Summary of Prescribing Information*

**Indications** Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

**Contraindications** Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

**Warnings** ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

***In Patients Without a History of Cardiac Failure:*** Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

***Ischemic Heart Disease:*** Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

***Bronchospastic Diseases:*** **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

***Major Surgery:*** The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

***Diabetes Mellitus:*** Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

***Thyrotoxicosis:*** Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

**Precautions** ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

***Drug Interactions:*** Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

***Long-Term Animal Studies:*** Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

***Usage in Pregnancy:*** Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

***Nursing Mothers:*** It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

***Usage in Children:*** Safety and effectiveness in children have not been established.

**Adverse Reactions** Most adverse effects have been mild and transient.

***Central Nervous System:*** Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

***Cardiovascular:*** Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

***Respiratory:*** Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

***Gastrointestinal:*** Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

***Allergic:*** Pruritus has occurred in less than 1 of 100 patients.

***Miscellaneous:*** Peyronie's disease has been reported in less than 1 of 100,000 patients. The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

***Potential Adverse Effects:*** In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

*Central Nervous System:* Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

*Cardiovascular:* Intensification of AV block (see **Contraindications**).

*Hematologic:* Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

*Allergic:* Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

*Miscellaneous:* Reversible alopecia.

*Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

**Dosage and Administration** Dosage of Lopressor should be individualized. The usual initial dose is 50 mg twice daily whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. Usual maintenance dosage is approximately 100 mg twice a day, with a range of 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients, especially when lower dosages are used, will experience a modest rise in blood pressure toward the end of the 12-hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. If control is not adequate, a larger dose, or three times daily therapy, may achieve better control. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

**How Supplied** Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

*Dispense in tight, light-resistant container (USP).*

**Geigy**

336-3610-A

hypertension, angina, and type A behavior personality. The mean follow-up period was 3.3 years and the dropout rate was 45% in each group. The relative risk of recurrence over 4 years in the high intensity group was 1.09 with 95% confidence limits of 0.61 and 1.96. These results indicate that a program of endurance training is no more effective than a program of low intensity activity in reducing the 4 year reinfarction rate in this study population.

**70 Predictors of Dropout From Cardiac Exercise Rehabilitation. Ontario Exercise-Heart Collaborative Study**

NEIL B. OLDRIDGE, ALLAN P. DONNER, CAROL W. BUCK, NORMAN L. JONES, GEORGE M. ANDREW, JOHN O. PARKER, DAVID A. CUNNINGHAM, TERENCE KAVANAGH, PETER A. RECHNITZER, and JOHN R. SUTTON

The dropout phenomenon in a multicenter clinical trial investigating the relation between exercise rehabilitation and recurrent myocardial infarction in men is described. The dropout rate was 46.5% over 3 years. Smoking and blue collar occupation were significant predictors of dropout; angina was a predictor only when reinfarctions were excluded. Identification of subgroups with an increased likelihood of dropout may optimize the potential of compliance-improving strategies in exercise rehabilitation trials and programs.

**75 Ventricular Electrical Instability: A Predictor of Death After Myocardial Infarction**

DAVID A. RICHARDS, DAVID V. CODY, ALAN R. DENNISS, PAUL A. RUSSELL, ALAN A. YOUNG, and JOHN B. UTHER

A standardized protocol of right ventricular programmed stimulation was used to assess ventricular electrical stability in 165 patients 6 to 28 days after acute myocardial infarction. Patients in whom ventricular fibrillation or sustained (>10 seconds) ventricular tachycardia (VT) was induced (38) were classified as unstable (23%). The remainder (127) were classified as stable (77%). The clinical profiles of the unstable and stable patients were initially similar. During the subsequent year, 8 unstable patients died instantaneously and 4 were resuscitated from spontaneous VT. No stable patient died instantaneously, and 2 developed spontaneous VT. Thus the risk of instantaneous death or spontaneous VT among unstable patients was 1:3, whereas the risk among stable patients was only 1:50 ($p < 0.001$). Prospective studies of antiarrhythmic therapy are required to determination whether sudden death can be prevented in unstable patients.

**81 Status of the Major Epicardial Coronary Arteries 80 to 150 Days After Percutaneous Transluminal Coronary Angioplasty. Analysis of 3 Necropsy Patients**

BRUCE F. WALLER, BRUCE M. McMANUS, H. JOEL GORFINKEL, JOAN C. KISHEL, EDWARD C. H. SCHMIDT, KENNETH M. KENT, and WILLIAM C. ROBERTS

Clinical and necropsy cardiac findings are described in 3 men who had percutaneous transluminal coronary angioplasty (PTCA) of the left anterior descending (LAD) coronary artery 80, 90, and 150 days before sudden death. Each patient had a decrease in the mean transstenotic coronary gradient (17, 38, and 43 mm Hg) and an angiographic increase in the LAD luminal diameter (55, 60, and 65%). At necropsy, the LAD coronary artery in the area of the PTCA in each patient was narrowed 76 to 95% in cross-sectional area by atherosclerotic plaques. No cracks in plaques or other lesions which may have resulted from the PTCA procedure were identified histologically in the LAD coronary artery of any patient.

## ARRHYTHMIAS AND CONDUCTION DISTURBANCES

**85 Electrophysiologic Testing in the Management of Survivors of Out-of-Hospital Cardiac Arrest**

FRED MORADY, MELVIN M. SCHEINMAN, DAVID S. HESS, RUEY J. SUNG, EDWARD SHEN, and WILLIAM SHAPIRO

In 45 patients who survived a cardiac arrest due to ventricular tachycardia (VT) or ventricular fibrillation, programmed ventricular stimulation induced sustained VT in 58% and nonsustained VT in 18%. Patients without inducible VT had no recurrent sudden death with treatment directed at the underlying heart disease. Serial electropharmacologic testing with conventional antiarrhythmic drugs was disappointing, with a low incidence (26%) of arrhythmia suppression. Among patients treated with amiodarone, 21 of 23 (91%) had no recurrence of VT or sudden death over a follow-up period of 18 ± 14 months (mean ± standard deviation). Chronic oral amiodarone therapy may supplant the need for serial drug testing in patients with inducible VT.

Continued on Page A28

90 **Quinidine for Ventricular Arrhythmias: Value of Electrophysiologic Testing**

JOHN P. DiMARCO, HASAN GARAN, and JEREMY N. RUSKIN

Eighty-nine patients with a history of ventricular tachycardia (VT) or ventricular fibrillation in response to programmed cardiac stimulation received quinidine in an attempt to suppress their arrhythmias. Quinidine at a mean serum concentration of 2.9 ± 0.8 μg/ml suppressed the initiation of VT during repeated ventricular stimulation in 30 of these patients. In an additional 8 patients, quinidine plus a second antiarrhythmic drug prevented the initiation of VT by ventricular stimulation. During chronic therapy, 32 of these 38 patients remained free of recurrent arrhythmia, while 3 had a clinical recurrence and 3 were forced to discontinue quinidine because of adverse effects. These data demonstrate that when patients are selected for chronic therapy on the basis of electrophysiologic studies, quinidine can provide long-term protection against recurrent arrhythmias.

96 **Enhanced Parasympathetic Tone Shortens Atrial Refractoriness in Man**

ERIC N. PRYSTOWSKY, GERALD V. NACCARELLI, WARREN M. JACKMAN, ROBERT L. RINKENBERGER, JAMES J. HEGER, and DOUGLAS P. ZIPES

Twelve patients were studied to determine the effects of enhanced vagal tone on human right atrial refractoriness. A lead neck collar connected to a vacuum source was placed around the patient's neck, and neck suction produced enhanced vagal tone. Atrial refractory periods were determined during high right atrial pacing. Induced neck suction increased spontaneous sinus cycle length from 837 ± 96 to 1,136 ± 273 ms ($p < 0.001$) and shortened the atrial effective refractory period from 241 ± 24 to 230 ± 20 ms ($p < 0.01$) and the atrial functional refractory period from 272 ± 32 to 262 ± 29 ms ($p < 0.01$). In 2 patients collar-induced decreases in atrial refractoriness and increases in spontaneous cycle length were prevented after atropine (0.03 mg/kg intravenously) was given. We conclude that enhanced vagal tone mediated through muscarinic receptors shortens atrial refractory periods in man.

101 **Effect of Local Lidocaine Anesthesia on Ventricular Escape Intervals During Permanent Pacemaker Implantation in Patients With Complete Heart Block**

BERNARD D. KOSOWSKY, SHAHID I. MUFTI, GURINDER S. GREWAL, RICHARD H. S. MOON, W. LINDA CASHIN, JOHN O. PASTORE, and K. RAMASWAMY

The role of subcutaneous lidocaine anesthesia in the occurrence of transient asystole during permanent pacemaker implantation was studied in 9 patients with complete heart block. Ventricular escape intervals were measured before and 10, 30, and 45 minutes after subcutaneous lidocaine administration for permanent pacemaker implantation. The total lidocaine dose ranged from 170 to 400 mg. Therapeutic blood levels were achieved in 7 patients. The mean ventricular escape interval before lidocaine was 2.06 ± 0.30 seconds, which increased to 3.80 ± 1.44 seconds ($p < 0.01$). The percent increase in maximal escape interval was directly related to the peak lidocaine level achieved. After lidocaine administration, 5 patients had asystole >4 seconds. Thus, subcutaneous lidocaine contributes to the occurrence of asystole seen during permanent pacemaker implantation even in the absence of previous asystole.

105 **Relation Between Late Potentials on the Body Surface and Directly Recorded Fragmented Electrograms in Patients With Ventricular Tachycardia**

MICHAEL B. SIMSON, WILLIAM J. UNTEREKER, SCOTT R. SPIELMAN, LEONARD N. HOROWITZ, NORMAN H. MARCUS, RITA A. FALCONE, ALDEN H. HARKEN, and MARK E. JOSEPHSON

The relation between directly recorded electrograms and late potentials recorded on the body surface with a signal-averaged electrocardiogram was studied in 8 patients with and 11 patients without ventricular tachycardia (VT). Four patients without VT, each with a previous myocardial infarction, had fragmented endocardial electrograms; the latest electrogram for each patient ended 87 ± 8 ms after QRS onset within the high amplitude portion of the filtered QRS complex. All VT patients had fragmented electrograms recorded, predominantly from endocardial sites; the latest fragmented electrogram for each patient ended 161 ± 40 ms after QRS onset. Late potentials recorded in 6 patients with VT and were shown to correlate in time with fragmented electrographic activity. Two VT patients did not have late potentials; 1 had left bundle branch block, and the other had brief fragmented electrograms. The late potential recorded on the body surface corresponds to delayed and fragmented electrographic activity.

The Burdick E 200 doesn't ask you to believe it's functioning correctly. It proves it by generating a sequence of test data, on command, for your evaluation.

The single-channel E 200 tests seven vital functions — sensitivity, timing printhead, alphanumeric printhead, time-constant, baseline shift, frequency response and paper speed. And the microprocessor technology that makes the automatic E 200 so easy to operate also performs its own internal checks.

The E 200 features a unique Touch-Entry keyboard with the latest in membrane switches, and each Touch-Entry key has an embossed frame for easy location. This ECG even responds with a 'beep' to acknowledge your commands.

During operation, the E 200 labels each lead clearly, notes sensitivity and filter setting, and prints a code of up to ten digits for positive patient identification.

How much do all these advanced features cost? Less than you'd expect. That's the Burdick commitment to deliver the latest in cardiograph technology at affordable prices.

To find out more about 'The Easy ECG', just ask.

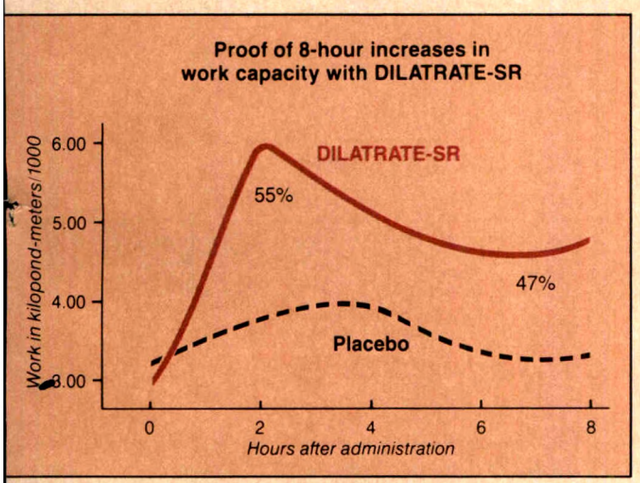
ONLY
DILATRATE®-SR
(isosorbide dinitrate)
HAS CLINICAL

n treadmill tests, DILATRATE-SR produced a 17% ncrease in mean total exercise duration within 2 hours; after 8 hours the increase was 20%.

### *Exercise duration and work capacity increased for a full 8 hours in angina patients**

In a double-blind, placebo-controlled study involving patients with chronic stable angina, significant improvement in exercise capacity was sustained for eight hours following administration of one 40 mg DILATRATE-SR capsule.[1]

This is the first study to demonstrate that a sustained-release nitrate formula can provide clinical effectiveness for a full eight hours. And, the advantage over placebo did not appear to be decreasing at the end of eight hours.



### *Increases in exercise tolerance translate into true patient benefits*

Exercise tolerance tests provide objective measurements of improvement in work capacity that can be correlated with the anginal patient's daily activities. These results demonstrate that DILATRATE-SR can provide a positive impact on your patient's lifestyle.

### *Clinical support of plasma level studies*

This clinical study supports previous blood assays which demonstrated that DILATRATE-SR provides significant plasma levels of ISDN for up to 12 hours.[2]

# PROOF: 8-hour antianginal activity*

A 20% increase in duration of treadmill exercise means another minute or two at higher speed on a steeper incline. When mean work performance was calculated, DILATRATE-SR provided a 47% increase at 8 hours.

### *A unique method of delivering isosorbide dinitrate*

DILATRATE-SR employs a unique delivery system — an advanced microdialyzing membrane that releases ISDN at a steady rate independent of gastric pH and enzymes. The water-activated membrane continually adjusts permeability to maintain constant nitrate release.

### *DILATRATE-SR simplifies antianginal therapy*

The proven sustained activity of DILATRATE-SR offers anginal patients convenient b.i.d. dosage and can reduce the need for sublingual nitroglycerin.

*Please see brief summary of full prescribing information on following page. For full prescribing information, consult package insert.

**Dilatrate®-SR**
(isosorbide dinitrate) 40 mg

**The clinically confirmed CONFIDENCE CAPSULE**

# Dilatrate®-SR
## (isosorbide dinitrate) 40 mg

**BRIEF SUMMARY**

Indications: Based on a review of this drug by the National Academy of Sciences – National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: When taken by the oral route, is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indication requires further investigation.

**CONTRAINDICATION:** Idiosyncrasy to this drug.

**WARNINGS:** Data supporting the use of nitrates and nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

**PRECAUTIONS:** Tolerance to this drug, and cross-tolerance to other nitrates or nitrites may occur.

In patients with functional or organic gastrointestinal hypermotility or malabsorption syndrome it is suggested that either the 5 mg. or 10 mg. oral tablets or 2.5 mg. or 5 mg. sublingual tablets be the preferred therapy.

**ADVERSE REACTIONS:** Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.

An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

For full prescribing information, consult package insert.

# MYOCARDIAL REVASCULARIZATION

## MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

**The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.**

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

## Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

The Irex Phased Array Real Time Imaging System

# SIMULTANEOUS DOPPLER
# A NEW DIMENSION IN CARDIAC IMAGING

**Simultaneous 2-D phased array imaging and CW or pulsed Doppler for noninvasive correlation of hemodynamics and anatomy**

Provides two complementary techniques—2-D to delineate cardiac structure, Doppler to evaluate blood flow velocity patterns—for global assessment of cardiac function.

You can noninvasively measure pressure gradients across obstructions and shunts, quantify relative cardiac output changes, and map flow patterns. Simultaneous display facilitates rapid examinations and permits accurate Doppler sample volume placement.

**Combined CW and pulsed Doppler for comprehensive flow measurements**

CW Doppler furnishes accurate measurements of high blood flow velocities, while pulsed Doppler provides precise sample location. Versatile spectrum analysis characterizes flow velocity patterns and verifies quality of the Doppler examination.

**Simultaneous 2-D/Doppler with one small dual-frequency transducer**

A single, small, lightweight transducer permits simultaneous 2-D and Doppler studies through all cardiac windows, and automatically optimizes the ultrasound frequency for both study modalities. Its extremely light, flexible cable permits easy angulation and lessens operator fatigue.

**Complete simultaneous documentation of all measurements**

Documentation is provided on videotape and superb quality Irex hard copy. This includes: videotapes of 2-D images and localized Doppler sample volume with Doppler audio signal; hard copy recordings of maximum and mean velocity traces; grey scale recordings of Doppler spectrum analysis and gated 2-D image depicting localized Doppler sample; time correlated with other data traces including ECG, phono, and pulse.

**Simultaneous phased array 2-D and superior dual derived M-modes**

In addition, you get fully diagnostic ECG, with 12 selectable leads; phono with two channels and eight filter settings; and pulse. All data channels are fully synchronized, and all perform simultaneously.

Irex systems provide incomparable value in meeting all your cardiodiagnostic needs. For details on the Irex Phased Array Real Time Imaging System, Irex System II for M-mode studies, 2-D applications, and cath lab applications, and the Irex Cardio 80® general-purpose microcomputer for cardiology, contact us today.

In the CCU, after conversion of VF...

# Bretylol® (bretylium tosylate)

## Follow-up therapy helps maintain stabilization

During the two or three days **after** conversion of ventricular fibrillation, the patient may still be electrically unstable. During this critical high risk period, **another** episode of VF may occur, completely unheralded.

### Good reasons to keep the VF patient on Bretylol follow-up therapy!

1. Bretylol raises the VF threshold almost three times control, protecting the heart from fibrillation.[1]*
   **No other agent has this dramatic effect.**
2. Bretylol also suppresses reentry, a major cause of VF by helping to equalize the electrophysiological differences between injured and normal ventricular tissue.[2]*
   **No other agent can do this.**

### And, Bretylol offers added benefit in treating the acute episode, too.

Bretylol, a first-line agent in the acute control of VF, should be used in the very first stages of VF, as soon as cardiopulmonary resuscitation and countershock have been attempted. Bretylol not only raises the fibrillation threshold...it reduces the energy required for defibrillation.[3,4]* Another critical difference in the Bretylol mechanism of action.

That's why it makes sense to use Bretylol to maintain stabilization in the CCU, as well as in the first few minutes of acute VF episodes.

There are no contraindications to the use of Bretylol in VF. Hypotension and postural hypotension have been the most frequently reported adverse reactions. Consult brief summary of prescribing information on the following page.

For further information, please contact the Medical Services Department, American Critical Care, a division of American Hospital Supply Corporation, 1600 Waukegan Road, McGaw Park, IL 60085, Phone 312/473-3000.

**Bretylol...adds a different and unique dimension in control of ventricular fibrillation**

**American Critical Care**

# Bretylol®
## (bretylium tosylate)

**Brief summary of prescribing information**

**INDICATIONS**—BRETYLOL is indicated in the prophylaxis and therapy of ventricular fibrillation.

BRETYLOL is also indicated in the treatment of life-threatening ventricular arrhythmias, such as ventricular tachycardia, that have failed to respond to adequate doses of a first-line antiarrhythmic agent, such as lidocaine.

Use of BRETYLOL should be limited to intensive care units, coronary care units or other facilities where equipment and personnel for constant monitoring of cardiac arrythmias and blood pressure are available.

Following injection of BRETYLOL there may be a delay of 20 minutes to 2 hours in the onset of antiarrhythmic action, although it appears to act within minutes in ventricular fibrillation. The delay in effect appears to be longer after intramuscular than after intravenous injection.

**CONTRAINDICATIONS**—There are no contraindications to use in treatment of ventricular fibrillation or life-threatening refractory ventricular arrhythmias.

**WARNINGS**—**1. Hypotension:** Administration of BRETYLOL regularly results in postural hypotension, subjectively recognized by dizziness, lightheadedness, vertigo or faintness. Some degree of hypotension is present in about 50% of patients while they are supine. Hypotension may occur at doses lower than those needed to suppress arrhythmias.

> Patients should be kept in the supine position until tolerance to the hypotensive effect of BRETYLOL develops. Tolerance occurs unpredictably but may be present after several days.

Hypotension with supine systolic pressure greater than 75 mm Hg need not be treated unless there are associated symptoms. If supine systolic pressure falls below 75 mm Hg, an infusion of dopamine or norepinephrine may be used to raise blood pressure. When catecholamines are administered, a dilute solution should be employed and blood pressure monitored closely because the pressor effects of the catecholamines are enhanced by BRETYLOL. Volume expansion with blood or plasma and correction of dehydration should be carried out where appropriate.

**2. Transient Hypertension and Increased Frequency of Arrhythmias:** Due to the initial release of norepinephrine from adrenergic postganglionic nerve terminals by BRETYLOL, transient hypertension or increased frequency of premature ventricular contractions and other arrhythmias may occur in some patients.

**3. Caution During Use with Digitalis Glycosides:** The initial release of norepinephrine caused by BRETYLOL may aggravate digitalis toxicity. When a life-threatening cardiac arrhythmia occurs in a digitalized patient, BRETYLOL should be used only if the etiology of the arrhythmia does not appear to be digitalis toxicity and other antiarrhythmic drugs are not effective. Simultaneous initiation of therapy with digitalis glycosides and BRETYLOL (bretylium tosylate) should be avoided.

**4. Patients with Fixed Cardiac Output:** In patients with fixed cardiac output (i.e., severe aortic stenosis or severe pulmonary hypertension) BRETYLOL should be avoided since severe hypotension may result from a fall in peripheral resistance without a compensatory increase in cardiac output. If survival is threatened by the arrhythmia, BRETYLOL may be used but vasoconstrictive catecholamines should be given promptly if severe hypotension occurs.

**USE IN PREGNANCY**—The safety of BRETYLOL in human pregnancy has not been established. However, as the drug is intended for use only in life-threatening situations, it may be used in pregnant women when its benefits outweigh the potential risk to the fetus.

**USE IN CHILDREN**—The safety and efficacy of this drug in children has not been established. BRETYLOL has been administered to a limited number of pediatric patients, but such use has been inadequate to define fully proper dosage and limitations for use.

**PRECAUTIONS**—**1. Dilution for Intravenous Use:** BRETYLOL should be diluted (one part BRETYLOL with four parts of Dextrose Injection, USP or Sodium Chloride Injection, USP) prior to intravenous use. Rapid intravenous administration may cause severe nausea and vomiting. Therefore, the diluted solution should be infused over a period greater than 8 minutes. In treating existing ventricular fibrillation BRETYLOL should be given as rapidly as possible and may be given without dilution.

**2. Use of Various Sites for Intramuscular Injection:** When injected intramuscularly, not more than 5 ml should be given in a site, and injection sites should be varied since repeated intramuscular injection into the same site may cause atrophy and necrosis of muscle tissue, fibrosis, vascular degeneration and inflammatory changes.

**3. Reduce Dosage in Impaired Renal Function:** Since BRETYLOL is excreted principally via the kidney, the dosage interval should be increased in patients with impaired renal function.

**ADVERSE REACTIONS**—Hypotension and postural hypotension have been the most frequently reported adverse reactions (see Warnings section). Nausea and vomiting occurred in about three percent of patients, primarily when BRETYLOL was administered rapidly by the intravenous route (see Precautions section). Vertigo, dizziness, light-headedness and syncope, which sometimes accompanied postural hypotension, were reported in about 7 patients in 1000.

Bradycardia, increased frequency of premature ventricular contractions, transitory hypertension, initial increase in arrhythmias (see Warnings section), precipitation of anginal attacks, and sensation of substernal pressure have also been reported in a small number of patients, i.e., approximately 1-2 patients in 1000.

Renal dysfunction, diarrhea, abdominal pain, hiccups, erythematous macular rash, flushing, hyperthermia, confusion, paranoid psychosis, emotional lability, lethargy, generalized tenderness, anxiety, shortness of breath, diaphoresis, nasal stuffiness and mild conjunctivitis, have been reported in about 1 patient in 1000. The relationship of BRETYLOL administration to these reactions has not been clearly established.

**HOW SUPPLIED**—NDC 0094-0012-10: 10 ml ampul containing 500 mg bretylium tosylate in Water for Injection, USP, pH adjusted, when necessary, with dilute hydrochloric acid or sodium hydroxide. Sterile, non-pyrogenic.

**The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.**

# Cardiac Bioprostheses

**Proceedings of the Second International Symposium**
**Rome, Italy, May 17-19, 1982**

**edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD**
**ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00**

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

## Who are the editors?

**Lawrence H. Cohn, MD,** is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

**Vincenzo Gallucci, MD,** is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

# radionuclide cardiography comes of age

# Apex 215M

## The Cardiologist's Own Nuclear Camera

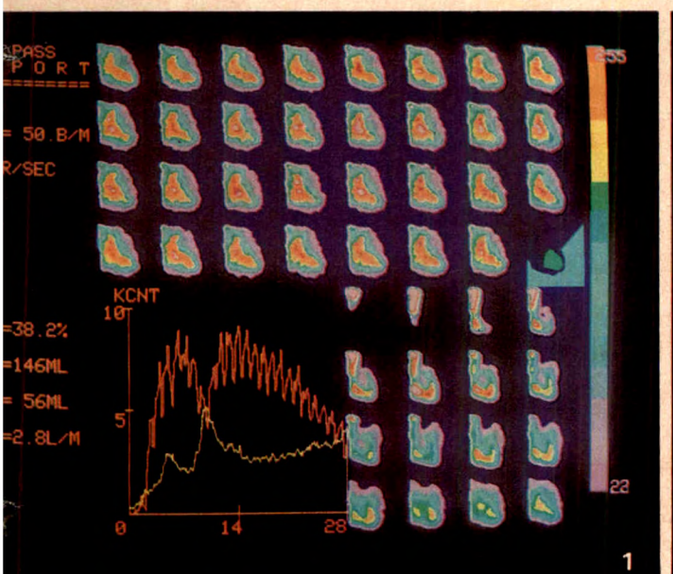
Nuclear Cardiology: it grows more authoritative every day. Apex 215M is fast becoming the cardiologist's first choice in nuclear imaging. And with good reason.

**Universal Cardiological Capability**

Specifically designed for cardiological use, Apex 215M is a compact digital nuclear camera — fully mobile and exceptionally maneuverable.

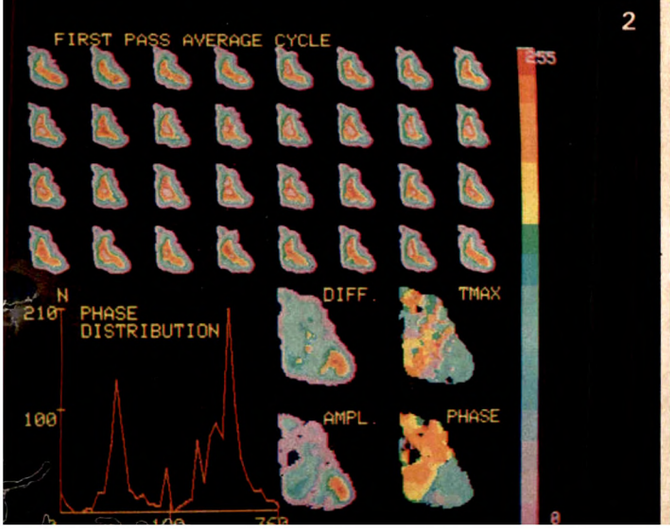
Apex 215M's image quality is far superior to that of any other camera. Clinical count rates in first-pass studies exceed 200K CPS. Resolutions of 1.8 mm bars are particularly valuable in Tc and Tl scintigraphic studies of myocardial infarction and ischemia. And superfast data handling enables rest/exercise equilibrium studies at 64 frames per cycle.

**Dedicated Cardiological Software**



Today's knowledgeable cardiologist appreciates Apex 215M's broad spectrum of dedicated software:

- Global and Regional Ejection Fraction
- End Diastole/Systole Volumes
- Paradox Imaging
- Fourier, Phase and Amplitude Imaging



and many more. And an entire new series of Apex cardiological programs is currently being tested.

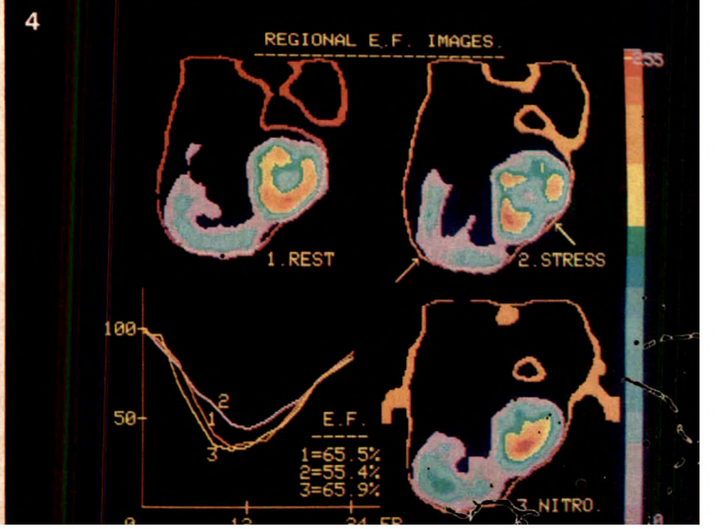
1



2

*Photos 1 & 2:* Apex 215M's high count rates enable superior definitive first-pass studies. Typical of its capabilities are global and regional ventricular function analysis and direct quantification through volume.

3

4

*Photos 3 & 4:* Apex 215M can clearly display various global and regional functions on a single image monitor. In these examples, ventricular functions in a resting heart appear above; the lower image compares the resting heart with two different intervention situations.

# CONTENTS

149 **Cryosurgery for Cardiac Arrhythmias: Acute and Chronic Effects on Coronary Arteries**

WILLIAM L. HOLMAN, MASATOSHI IKESHITA, ROSS M. UNGERLEIDER, PETER K. SMITH, RAYMOND E. IDEKER, and JAMES L. COX

In this study, the acute and chronic effects of cryothermia on coronary arterial patency and integrity were examined. In the acute study, coronary arterial and regional myocardial blood flow were determined during and immediately after cryothermic exposure. Arterial occlusion occurred 20 ± 4 seconds after institution of cryothermia, and patency returned 29 ± 8 seconds after termination of cryothermia. Analysis of postthaw regional myocardial blood flow showed no evidence of embolization of debris after thawing. In the chronic study, coronary arteries subjected to cryothermia were examined histologically 48 hours, 2 weeks, or 6 months postoperatively. Intimal hyperplasia was often present at the site of the cryolesion. This intimal hyperplasia was most marked in lesions created during hyperthermic cardioplegic arrest. Thus, cryothermia-induced coronary arterial damage may produce hemodynamically significant coronary arterial stenosis, and caution should be exercised when it is necessary to create cryolesions in the vicinity of major coronary arteries.

156 **Intravenous Amiodarone in the Acute Treatment of Recurrent Symptomatic Ventricular Tachycardia**

FRED MORADY, MELVIN M. SCHEINMAN, EDWARD SHEN, WILLIAM SHAPIRO, RUEY J. SUNG, and LORENZO DiCARLO

Fifteen patients had frequent episodes of ventricular tachycardia refractory to at least 2 conventional antiarrhythmic drugs. All patients received an initial bolus of 5 mg/kg of amiodarone. Seven patients also received a continuous infusion of 600 to 1,000 mg of amiodarone over 12 to 24 hours. Additional doses depended on the clinical response. Previously ineffective antiarrhythmic drugs were continued in 11 of 15 patients. In 12 of 15 patients there was acute control of ventricular tachycardia by intravenous amiodarone either alone or in combination with previously ineffective drugs. The use of intravenous amiodarone represents a significant advance in the acute treatment of frequent life-threatening ventricular tachycardia refractory to other drugs.

## SYSTEMIC HYPERTENSION

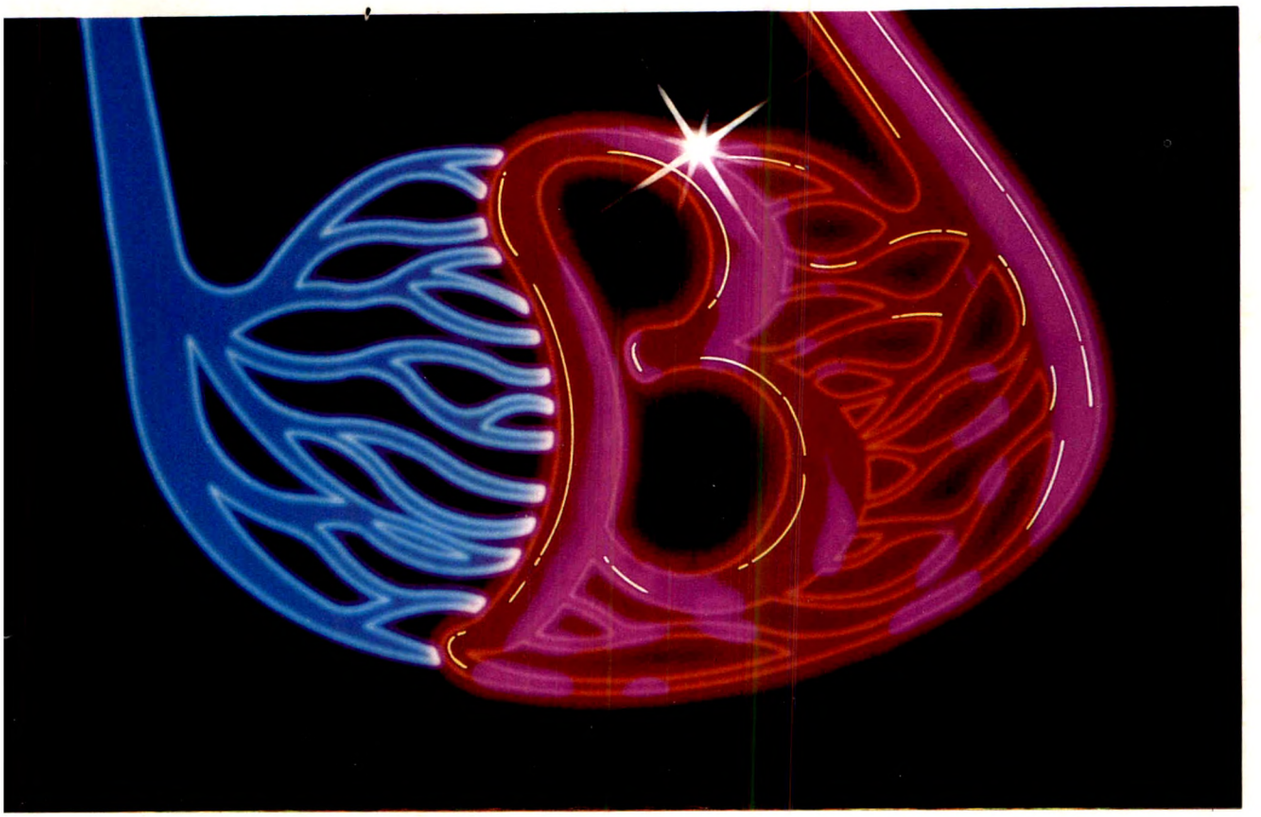
161 **Alterations in Left Ventricular Filling With Beta-Adrenergic Blockade**

FETNAT M. FOUAD, MAREK J. SLOMINSKI, ROBERT C. TARAZI, and JOE GALLAGHER

The cardiac and hemodynamic effects of 1 month of treatment with beta blockage (metoprolol in 8 patients and nadolol in 13 patients) in hypertension revealed differences in the ventricular volume curves between responders and nonresponders. Responders maintained the same ejection velocity and had a more rapid early filling rate. In contrast, nonresponders showed a reduced velocity of ejection and a slower rate of ventricular filling. Thus, alteration of ventricular function with beta blockade can be overshadowed by blood pressure reduction.

165 **Intravascular Volume, Extracellular Fluid Volume, and Total Body Water in Obese and Nonobese Hypertensive Patients**

JOCELYNE H. RAISON, APOSTOLOS D. ACHIMASTOS, JEAN E. BOUTHIER, GERARD M. LONDON, and MICHEL E. SAFAR



Intraarterial blood pressure, plasma volume, extracellular and interstitial (IFV) fluid volumes, and total and intracellular (IBW) body water were evaluated in 47 men: 16 obese hypertensive patients, 16 nonobese hypertensive patients and 15 normal subjects of similar age. In obese hypertensive subjects, the IBW/IFV ratio was significantly increased ($p < 0.01$) in comparison with both control subjects and nonobese hypertensive patients. After body weight reduction, blood pressure ($p < 0.01$), heart rate ($p < 0.05$), and the IBW/IFV ratio ($p < 0.01$) significantly decreased. The decrease in the ratio was due to an absolute increase in interstitial fluid volume, related to a shift of fluid volume from the intracellular to the interstitial space. Thus, obese hypertensive patients have an increased water cell content, causing an altered partition between the intracellular and the interstitial spaces.

171 **Relation of Hemodynamic Load to Left Ventricular Hypertrophy and Performance in Hypertension**

RICHARD B. DEVEREUX, DANIEL D. SAVAGE, IRENE SACHS, and JOHN H. LARAGH

One hundred untreated patients with essential hypertension were studied by echocardiography and cuff blood pressure to assess the relation between hemodynamic load and left ventricular hypertrophy and performance. Indexes of left ventricular hypertrophy were poorly related to resting blood pressure ($r = 0.16$ to 0.32). However,

# Visken® (pindolol)

**the only beta blocker that reduces blood pressure and total peripheral resistance**

## Here's the difference:

### Blood pressure

Blood pressure equals cardiac output times total peripheral resistance.

$$bp = co \times tpr$$

### Visken (pindolol)

Visken (pindolol) is the only beta blocker that reduces blood pressure while maintaining resting cardiac output and reducing total peripheral resistance during long-term therapy.

$$\underline{bp} = \underline{\overline{co}} \times \underline{tpr}$$

### All other beta blockers

All other beta blockers reduce blood pressure, and reduce cardiac output with an initial reflex rise in total peripheral resistance and a subsequent return to baseline in many cases.

$$\underline{bp} = \underline{co} \times \underline{\overline{tpr}}$$

Please see last page of this advertisement for brief summary of prescribing information.

# Here's the result:

## Reduced blood pressure

U.S. studies at 29 major medical centers[1] have shown that Visken (pindolol) is an effective antihypertensive. It is as effective as propranolol in normalizing blood pressure (dbp≤90 mmHg) when used alone. It is also effective when used in combination with a diuretic.

This antihypertensive effectiveness is supported by 13 years of clinical use throughout the world. In fact, Visken (pindolol) is the #2 beta blocker in the rest of the world.

## Reduced peripheral resistance

Studies of 178 patients treated with Visken (pindolol) for at least two weeks have shown that Visken therapy reduces total peripheral resistance.[1]

## Reduction of exercise-induced tachycardia

Like other beta blockers, Visken (pindolol) blocks stimulation by catecholamines to reduce exercise-induced increases in systolic blood pressure and heart rate.

# Prescribing information:

## Available in 5 mg and 10 mg tablets

## Convenient bid dosage

Dosage should be titrated on an individual basis. Many patients respond to 10-30 mg a day in divided doses.

Please see last page of this advertisement for brief summary of prescribing information.

# New Visken® (pindolol)

*Before prescribing or administering, see package circular for full product information. The following is a brief summary.*

**INDICATIONS AND USAGE**
Visken (pindolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide type diuretic.

**CONTRAINDICATIONS**
Visken (pindolol) is contraindicated in: 1) bronchial asthma; 2) overt cardiac failure; 3) cardiogenic shock; 4) second and third degree heart block; 5) severe bradycardia; (see Warnings).

**WARNINGS**
**Cardiac Failure:** Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, Visken (pindolol) can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

**In Patients Without A History of Cardiac Failure:** In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Visken (pindolol) therapy should be withdrawn (gradually if possible).

**Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal:** Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered Visken (pindolol), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Visken (pindolol) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Visken (pindolol) therapy abruptly even in patients treated only for hypertension.

**Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—Patients with Bronchospastic Diseases Should in General Not Receive Beta-Blockers:** Visken (pindolol) should be administered with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

**Major Surgery:** Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase the risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, beta-blockers should be withdrawn well before surgery takes place. In the event of emergency surgery, the anesthesiologist should be informed that the patient is on beta-blocker therapy. The effects of Visken* (pindolol) can be reversed by administration of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

**Diabetes and Hypoglycemia:** Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust the dose of antidiabetic drugs.

**Thyrotoxicosis:** Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta-blockade which might precipitate a thyroid crisis.

**PRECAUTIONS**
**Impaired Renal or Hepatic Function:** Beta-blocking agents should be used with caution in patients with impaired hepatic or renal function. Poor renal function has only minor effects on Visken (pindolol) clearance, but poor hepatic function may cause blood levels of Visken (pindolol) to increase substantially.

**Information for Patients:** Patients, especially those with evidence of coronary artery insufficiency, should be warned against interruption or discontinuation of Visken (pindolol) therapy without the physician's advice. Although cardiac failure rarely occurs in properly selected patients, patients being treated with beta-adrenergic blocking agents should be advised to consult the physician at the first sign or symptom of impending failure.

**Drug Interactions:** Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients receiving Visken (pindolol) plus a catecholamine depleting agent should, therefore, be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Visken (pindolol) has been used with a variety of antihypertensive agents, including hydrochlorothiazide, hydralazine, and guanethidine without unexpected adverse interactions.

**Carcinogenesis, Mutagenesis, Impairment of Fertility:** In chronic oral toxicologic studies (one to two years) in mice, rats, and dogs, Visken (pindolol) did not produce any significant toxic effects. In two-year oral carcinogenicity studies in rats and mice in doses as high as 59 mg/kg/day and 124 mg/kg/day (50 and 100 times the maximum recommended human dose), respectively, Visken (pindolol) did not produce any neoplastic, preneoplastic, or nonneoplastic pathologic lesions. In fertility and general reproductive performance studies in rats, Visken (pindolol) caused no adverse effects at a dose of 10 mg/kg.

In the male fertility and general reproductive performance test in rats, definite toxicity characterized by mortality and decreased weight gain was observed in the group given 100 mg/kg/day. At 30 mg/kg/day, decreased mating was associated with testicular atrophy and/or decreased spermatogenesis. This response is not clearly drug related, however, as there was no dose response relationship within this experiment and no similar effect on testes of rats administered Visken (pindolol) as a dietary admixture for 104 weeks. There appeared to be an increase in prenatal mortality in males given 100 mg/kg but development of offspring was not impaired.

In females administered Visken (pindolol) prior to mating through day 21 of lactation, mating behavior was decreased at 100 mg/kg and 30 mg/kg. At these dosages there also was increased mortality of offspring. Prenatal mortality was increased at 10 mg/kg but there was not a clear dose response relationship in this experiment. There was an increased resorption rate at 100 mg/kg observed in females necropsied on the 15th day of gestation.

**Pregnancy—Category B:** Studies in rats and rabbits exceeding 100 times the maximum recommended human doses, revealed no embryotoxicity or teratogenicity. Since there are no adequate and well-controlled studies in pregnant women, and since animal reproduction studies are not always predictive of human response, Visken (pindolol), as with any drug, should be employed during pregnancy only if the potential benefit justifies the potential risk to the fetus.

**Nursing Mothers:** Since Visken (pindolol) is secreted in human milk, nursing should not be undertaken by mothers receiving the drug.

**Pediatric Use:** Safety and effectiveness in children have not been established.

**CLINICAL LABORATORY**
Minor persistent elevations in serum transaminases (SGOT, SGPT) have been noted in 7% of patients during Visken (pindolol) administration, but progressive elevations were not observed and liver injury has not been reported in the medical literature over a ten (10) year period of marketing. Alkaline phosphatase, lactic acid dehydrogenase (LDH) and uric acid are also elevated on rare occasions. The significance of these findings is unknown.

**ADVERSE REACTIONS**
Most adverse reactions have been mild. The incidences listed in the following table are derived from 12 week comparative double-blind, parallel design trials in hypertensive patients given Visken (pindolol) as monotherapy, given various active control drugs as monotherapy, or given placebo. Data for Visken (pindolol) and the positive controls were pooled from several trials because no striking differences were seen in the individual studies, with one exception. The frequency of edema was noticeably higher in positive control trials (16% Visken (pindolol) vs 9% positive control) than in placebo controlled trials (6% Visken (pindolol) vs 3% placebo). The table includes adverse reactions reported in greater than 2% of Visken (pindolol) patients and other selected important reactions.

| Body System/ Adverse Reaction | Total (Volunteered and Elicited) Visken (pindolol) (N = 322) % | Active Controls* (N = 188) % | Placebo (N = 78) % |

*Active Controls: Patients received either propranolol, ∝-methyldopa or a diuretic (hydrochlorothiazide or chlorthalidone).

The following selected (potentially important) adverse reactions were seen in 2% or fewer patients and their relationship to Visken (pindolol) is uncertain. AUTONOMIC NERVOUS SYSTEM: hyperhidrosis; CARDIOVASCULAR: bradycardia, claudication, cold extremities heart block, hypotension, syncope, tachycardia; GASTROINTESTINAL: diarrhea, vomiting; RESPIRATORY: wheezing; UROGENITAL: impotence, pollakiuria; MISCELLANEOUS: eye discomfort or burning eyes.

**POTENTIAL ADVERSE EFFECTS**
In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agen and should be considered potential adverse effects of Visken (pindolol).

**Central Nervous System:** Reversible mental depressi progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, shor term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

**Cardiovascular:** Intensification of AV block. See CONTRAINDICATIONS.

**Allergic:** Erythematous rash; fever combined with achi and sore throat; laryngospasm; respiratory distress.

**Hematologic:** Agranulocytosis; thrombocytopenic and nonthrombocytopenic purpura.

**Gastrointestinal:** Mesenteric arterial thrombosis; ischemic colitis.

**Miscellaneous:** Reversible alopecia; Peyronie's diseas

The oculomucocutaneous syndrome associated with th beta-blocker practolol has not been reported with Viske (pindolol) during investigational use and extensive foreign experience amounting to over 4 million patient-years.

**OVERDOSAGE**
No specific information on emergency treatment of overdosage is available. Therefore, on the basis of the pharmacologic actions of Visken (pindolol), the followin general measures should be employed as appropriate i addition to gastric lavage:

**Excessive Bradycardia:** administer atropine; if there i no response to vagal blockade, administer isoproterenc cautiously.

**Cardiac Failure:** digitalize the patient and/or administe diuretic. It has been reported that glucagon may be use ful in this situation.

**Hypotension:** administer vasopressors, e.g., epinephrine or levarterenol, with serial monitoring of blood pres sure. (There is evidence that epinephrine may be the drug of choice.)

**Bronchospasm:** administer a $beta_2$ stimulating agent such as isoproterenol and/or a theophylline derivative.

A case of an acute overdosage has been reported with an intake of 500 mg of Visken (pindolol) by a hypertensive patient. Blood pressure increased and heart rate was ⩾80 beat/min. Recovery was uneventful. In anothe case 250 mg of Visken (pindolol) was taken with 150 m diazepam and 50 mg nitrazepam, producing coma and hypotension. The patient recovered in 24 hours.

**DOSAGE AND ADMINISTRATION**
The dosage of Visken (pindolol) should be individualize The recommended initial dose of Visken (pindolol) is 10 mg b.i.d. alone or in combination with other antihyperter sive agents. Many patients will respond to 15 mg per da (5 mg t.i.d.). The antihypertensive response usually occurs within the first week of treatment. If a satisfactor reduction in blood pressure does not occur within 2-3 weeks, the dose may be adjusted in increments of 10 m per day at 2-3 week intervals up to a maximum of 60 m per day.

**HOW SUPPLIED**
White, round, scored tablets: 5 mg and 10 mg, packaged of 100. 5 mg tablets embossed "VISKEN 5" on one side, and "78-111" and scored on other side (NDC 0078-0111-05). 10 mg tablets embossed "VISKEN 10" or one side, and "78-73" and scored on other side (NDC 0078-0073-05). [VIS-Z2 9/1-82]

**Pharmaceutical Division**
**SANDOZ, INC.**
East Hanover, NJ 07936

VIS-1182-

end-diastolic relative wall thickness, an index of concentric hypertrophy, was directly related to peripheral resistance ($r = 0.52$, $p < 0.001$) and inversely to cardiac output ($r = -0.47$, $p < 0.001$). Left ventricular fractional systolic shortening was unrelated to blood pressure or left ventricular mass, but showed a close inverse relation with end-systolic wall stress ($r = -0.71$, $p < 0.001$). It is concluded that resting blood pressure correlates poorly with left ventricular hypertrophy or function in patients with hypertension. However, the "typical" hypertensive abnormalities of concentric left ventricular hypertrophy and elevated peripheral resistance appear pathophysiologically interdependent, and left ventricular performance is dependent on compensatory hypertrophy, which keeps wall stress normal.

## CONGESTIVE HEART FAILURE

**177 Failure of Dobutamine to Increase Exercise Capacity Despite Hemodynamic Improvement in Severe Chronic Heart Failure**

CAROL S. MASKIN, ROBERT FORMAN, EDMUND H. SONNENBLICK, WILLIAM H. FRISHMAN, and THIERRY H. LeJEMTEL

The acute hemodynamic and metabolic effects of dobutamine administered during upright, graded bicycle exercise were studied in 8 patients with severe chronic heart failure. During exercise performed with administration of dobutamine, the cardiac index was significantly greater than during control period exercise, $3.23 \pm 0.78$ versus $2.67 \pm 0.59$ liters/min/m$^2$ ($p < 0.001$), while the arteriovenous oxygen difference was lower, $11.2 \pm 2.1$ versus $12.5 \pm 2.4$ ml/100 ml ($p < 0.01$). Although dobutamine tended to increase maximal oxygen uptake compared with control period exercise, it did not significantly increase exercise capacity. Thus, administration of dobutamine to patients with severe chronic heart failure increased the cardiac index during maximal exercise but failed to increase exercise capacity. Since the arteriovenous oxygen difference is reduced, dobutamine probably augments blood flow to the nonexercising tissues and not to the actively metabolizing muscles.

**183 Quantitative Differences in the Hemodynamic Effects of Captopril and Nitroprusside in Severe Chronic Heart Failure**

MILTON PACKER, JOSE MELLER, NORMA MEDINA, and MADELINE YUSHAK

The hemodynamic effects of oral captopril and intravenous nitroprusside were compared in 15 patients with severe chronic heart failure. At doses of both drugs titrated to produce similar decreases in systemic vascular resistance, nitroprusside produced greater increases in cardiac index but smaller decreases in mean arterial pressure than did captopril. This finding was due to a significant decrease in heart rate with captopril (not seen with nitroprusside), since changes in stroke volume index with both drugs were similar. Nitroprusside decreased pulmonary arteriolar resistance significantly, whereas captopril did not. This finding helped explain the smaller decreases in right ventricular filling pressure with captopril; yet, the decreases in left ventricular filling pressure with captopril were greater than with nitroprusside. These data indicate that angiotensin, in addition to its direct systemic arterial vasoconstrictor actions, exerts positive chronotropic effects and alters ventricular compliance but has minimal direct effects on the limb venous circulation and on the pulmonary circulation.

## CARDIOMYOPATHY

**189 Relation of Electrocardiographic Abnormalities and Patterns of Left Ventricular Hypertrophy Identified by 2-Dimensional Echocardiography in Patients With Hypertrophic Cardiomyopathy**

BARRY J. MARON, JAMES K. WOLFSON, ELISABETTA CIRÓ, and PAOLO SPIRITO

Distribution of left ventricular hypertrophy was assessed by wide-angle, 2-dimensional echocardiography in 153 patients with hypertrophic cardiomyopathy and compared with the scalar electrocardiogram in the same patients. The most common electrocardiographic alterations were S-T segment changes and T-wave inversion (61%), left ventricular hypertrophy (47%), abnormal Q waves (25%), and left atrial enlargement (24%). Left ventricular hypertrophy on electrocardiography was most common in patients with the most extensive distribution of the left ventricular hypertrophy involving substantial portions of both the ventricular septum and the left ventricular free wall (sensitivity 74%). The majority of patients with hypertrophic cardiomyopathy and normal electrocardiograms had particularly localized hypertrophy. Abnormal Q waves were significantly more common in patients without hypertrophy of the anterior basal septum, and hence cannot be explained on the basis of ventricular septal hypertrophy alone. No single electrocardiographic abnormality is characteristic of a population of patients with hypertrophic cardiomyopathy, and 2-dimensional echocardiography clarifies the significance of certain electrocardiographic patterns.

## EXPERIMENTAL STUDIES

**195 Comparative Effects of Nifedipine, Verapamil, and Diltiazem on Experimental Pulmonary Hypertension**

THOMAS E. YOUNG, LUCY J. LUNDQUIST, ELLIOT CHESLER, and E. KENNETH WEIR

This experimental study compared the hemodynamic effects of 3 calcium channel blocking agents (diltiazem, nifedipine, and verapamil) in 2 models of pulmonary hypertension in the anesthesized dog. The agents were given intravenously at 3 dose levels, either before acute hypoxic pulmonary vasoconstriction or before the stimulation of pulmonary hypertension by an infusion of prostaglandin $F_{2\alpha}$. During acute hypoxic pulmonary hypertension, verapamil decreased cardiac output by 30% ($p < 0.01$) without appreciably altering pulmonary arterial pressure. Nifedipine decreased hypoxic pulmonary vascular resistance to normoxic values ($p < 0.01$). Diltiazem administration produced no change in hypoxic pulmonary hemodynamics. During pulmonary hypertension stimulated by prostaglandin $F_{2\alpha}$, high dose verapamil tended to increase pulmonary vascular resistance. Nifedipine, however, completely blocked pulmonary vasoconstriction by decreasing pulmonary vascular resistance to pre-prostaglandin $F_{2\alpha}$ levels ($p < 0.01$). Again, diltiazem produced no change in pulmonary hemodynamics. Thus nifedipine appeared to be a more effective pulmonary vasodilator than verapamil or diltiazem.

**201 Compensatory Cardiac Mechanisms Evoked by Septal Ischemia in Dogs**

MALFRID MOLAUG, ODD GEIRAN, and FREDRIK KIIL

The cardiac responses to selective septal ischemia were studied in anesthesized open-chest dogs. Segment lengths were measured ultrasonically in the interventricular septum and the right and left ventricular free walls. At an average left ventricular end-diastolic pressure of 3 mm Hg, septal ischemia did not reduce stroke volume significantly, whereas left ventricular end-diastolic segment length increased 3%. This stimulation of the Frank-Starling mechanism counteracted the loss of septal function. After blood volume expansion to a left ventricular end-diastolic pressure of 7 mm Hg, end-diastolic dimensions in the left free wall did not increase and stroke volume decreased during septal ischemia. Ultrasonic recordings of the septum to right ventricular free wall distance showed increased systolic excursions and reduced end-systolic distance after occlusion of the septal artery, indicating paradoxical movement of the ischemic septum, which seems to act as a passive diaphragm pump on the right ventricle.

**207 Mechanisms of Spontaneous and Induced Ventricular Arrhythmias in the 24-Hour Infarcted Dog Heart**

BENJAMIN J. SCHERLAG, GLENN KABELL, JOHANNES BRACHMANN, LURA HARRISON, and RALPH LAZZARA

Two kinds of ventricular arrhythmias were consistently found in 14 dogs studied 1 day after left anterior descending coronary artery ligation. In the open-chest, anesthetized dog, electrocardiographic leads and electrograms from the infarct and normal zones were monitored. Spontaneous ventricular tachycardias were recorded which were irregular and multiform (average rate 154 ± 26 beats/min). In the same dogs, 3 ventricular paced beats at rates >300 beats/min induced rapid, uniform ventricular tachycardias (average rate 345 ± 17 beats/min). Only during the latter could continuous electrical activity within the interectopic intervals suggestive of a reentrant mechanism be consistently recorded. This experimental preparation is compared with ventricular arrhythmias described in clinical reports, and insights into the mechanism of entrainment of ventricular tachycardia are demonstrated.

## METHODS

**215 Can Tracking of Contrast Echocardiographic Targets Be Used to Measure Intracardiac Flow Velocities?**

LILLIAM M. VALDES-CRUZ, DAVID J. SAHN, SUZANA HOROWITZ, DANIEL C. FISHER, STANLEY J. GOLDBERG, and HUGH D. ALLEN

Recent reports have suggested that the slopes of linearly moving echocardiographic contrast targets (microbubbles) can be used to predict flow velocities in the right heart. This study assessed the accuracy of velocities measured with contrast echocardiography by comparing them with those recorded with a previously calibrated quantitative range gated 2-dimensional echocardiographic Doppler flow meter. Venous saline echocardiographic contrast injections and Doppler studies were performed in 10 cardiac patients, aged 6 months to 16 years,

# Baseline anginal therapy simplified

## Approximately 75% of angina patients were successfully controlled on the starting dosage—one Transderm-Nitro 5

*Once-daily application of Transderm-Nitro* was shown to provide effective 24-hour baseline therapy in the step-care approach to angina in a survey* of over 1,000 physicians with more than 10,000 patients under treatment.

Orthostatic hypotension may indicate nitroglycerin overdosage; reduce dosage if symptoms occur. Nitrates are contraindicated in patients with increased intraocular pressure. Withdrawal should be gradual if treatment is terminated. Do not apply to distal parts of the arms and legs.

## Transderm®-Nitro (nitroglycerin)
**Transdermal Therapeutic System**

### DESCRIPTION
Transderm-Nitro (nitroglycerin) transdermal therapeutic system is a flat unit designed to provide controlled release of nitroglycerin through a semipermeable membrane continuously for 24 hours following application to intact skin. Nitroglycerin (glyceryl trinitrate) is a prompt-acting vasodilator for the relief and prevention of anginal attacks. Systems are rated to release *in vivo* 5 and 10 mg nitroglycerin over 24 hours and are in sizes of 10 and 20 $cm^2$ respectively.

One-fifth of the total nitroglycerin in the system is delivered transdermally to the patient over 24 hours; the remainder serves as the thermodynamic energy source to release the drug and remains in the system. The rated release of drug is dependent upon the area of the system; 0.5 mg nitroglycerin is delivered *in vivo* for every $cm^2$ of system size.

The Transderm-Nitro system comprises four layers as shown below. Proceeding from the visible surface towards the surface attached to the skin, these layers are: 1) a tan-colored backing layer (aluminized plastic) that is impermeable to nitroglycerin; 2) a drug reservoir containing nitroglycerin adsorbed on lactose, colloidal silicon dioxide, and silicone medical fluid; 3) an ethylene/vinyl acetate copolymer membrane that is permeable to nitroglycerin; and 4) a layer of hypoallergenic silicone adhesive. Prior to use, a protective peel strip is removed from the adhesive surface.

Cross section of the system:

### ACTIONS
When the Transderm-Nitro system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before being inactivated by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilatation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation and consequent reduced cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In clinical studies transdermal absorption of nitroglycerin from a nitroglycerin system occurred in a continuous and well-controlled manner, for a minimum of 24 hours. Therapeutic effect can be anticipated 30 minutes after application of the system and to be maintained for 30 minutes after its removal.

### INDICATIONS AND USAGE
Transderm-Nitro system is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

### CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

### WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring. In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

### PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

### ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist, the dose should be reduced or use of the product discontinued.

### DOSAGE AND ADMINISTRATION
Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.

The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response.

The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.

Do not store above 86°F (30°C).

### PATIENT INSTRUCTIONS FOR APPLICATIONS
A patient leaflet is supplied with the systems.

### HOW SUPPLIED

who had undergone operation for lesions in the left side of the heart. Instantaneous and peak velocities were determined at time-matched systolic points in cardiac cycles of identical R-R intervals. Significant but low-level correlations were found between contrast echocardiography and Doppler instantaneous ($r = +0.45$) or peak ($r = +0.18$) systolic velocities. The results suggest that while contrast echo microbubbles can be measured to yield a velocity, they do not behave like moving red blood cells which reflect ultrasound to produce a Doppler shift. Therefore, contrast echocardiography does not reliably measure flow velocities in the right heart.

**219 Cardiac Localization of Transvascular Bioptome Using 2-Dimensional Echocardiography**

JAMES W. FRENCH, RICHARD L. POPP, and PAUL T. PITLICK

Transvascular endomyocardial biopsy was performed in 7 children with heart muscle disease using both fluoroscopy and 2-D echocardiography to orient the bioptome. Twelve procedures (1 left ventricular and 11 right ventricular biopsies) were performed in these patients, aged 6 months to 18 years. There were no complications using the fluoroscopic-echocardiographic technique. By adding 2-D echocardiographic monitoring to the biopsy procedure, exposure to ionizing radiation was reduced, and localization of the bioptome with respect to intracardiac structures was more precise than with fluoroscopy alone.

**224 Validation of the Angiographic Accuracy of Digital Left Ventriculography**

ALLEN B. NICHOLS, ERIC C. MARTIN, THOMAS P. FLES, KAREN M. STUGENSKY, LAWRENCE A. BALANCIO, WILLIAM J. CASARELLA, and MELVIN B. WEISS

The angiographic accuracy of digital subtraction left ventriculograms, performed by intraventricular injection of 7 ml contrast medium diluted in saline solution, was validated in 28 patients undergoing conventional cineangiographic left ventriculography. Left ventricular volumes calculated from digital ventriculograms correlated highly with volumes calculated from conventional ventriculograms: end-diastolic volume ($r = 0.97$, end-systolic volume ($r = 0.97$), stroke volume ($r = 0.95$), ejection fraction ($r = 0.97$), and segmented left ventricular contraction ($r = 0.81$). After digital left ventriculography with diluted contrast medium, left ventricular pressures were unchanged and patients had no discomfort. Thus, the contrast enhancement afforded by digital subtraction angiography provides high resolution ventriculograms with markedly reduced doses of contrast medium, obviating the hemodynamic effects of conventional doses of contrast medium. This approach permits accurate measurement of left ventricular volumes, stroke volume, and ejection fraction and accurate assessment of left ventricular segmental contraction, without injection of large doses of contrast medium.

**MISCELLANEOUS TOPICS**

**231 In Vivo Ultrasonic Tissue Characterization of Human Intracardiac Masses**

STEPHEN E. GREEN, LINDA F. JOYNT, PETER J. FITZGERALD, DAVID S. RUBENSON, and RICHARD L. POPP

Noninvasive tissue characterization was attempted in vivo to separate both apical mural thrombi from the instrument-generated spurious signals seen on most 2-dimensional ultrasonoscopes, and atrial thrombi from atrial neoplasms. A stochastic analysis of the digitized echocardiographic signals from 15 patients was performed. In 10 subjects with 2-dimensional echocardiograms suggesting mural thrombi, surgery or necropsy confirmed thrombi in 6 and revealed no thrombi (designated artifact) in 4. The amplitude histograms suggested a totally random probability density function in 5 of 6 thrombi and suggested nonrandom probability density function in all 4 artifacts. All 5 neoplasms showed nonrandom probability density function. A method for in vivo ultrasonic tissue characterization to help differentiate thrombi from artifact or neoplasm is described.

# Intracoronary Infusion

## American Edwards Takes the Technology Further Than Ever Before

With over a million myocardial infarcts in the U.S. every year and an associated 30 percent mortality rate, researchers have begun concentrating their efforts on drug lysis of intracoronary thrombi as a promising new avenue of patient management.[1,2]

**Introducing the Ganz-Edwards™ Coronary Infusion Catheter**

Advancement of the Coronary Infusion Catheter through an angiography catheter, already in place at the ostium, permits drug infusion inside the coronary arteries at the exact site of the clot.

Because delivery is so specific, drug dilution is minimized. Shunting of the thrombolytic agent away from the target area into proximal branches is dramatically reduced.[3]

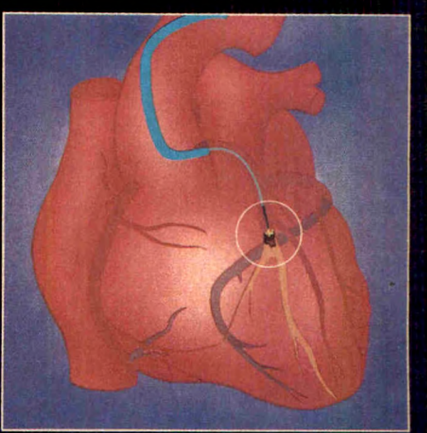
Concentration of the thrombolytic agent the target area substantially accelerates clot lysis, so critical in myocardial salvage.[3]

**Pressure Monitoring Combined with a Radiopaque, Atraumatic Tip**

With sub-selective coronary infusion at the forefront of technology, the Ganz-Edwards Coronary Infusion Catheter improves the technique with these added benefits:

] An atraumatic distal 20 cm for safer dvancement into distal locations of the oronary vasculature.
] A reduced lumen size for continuous ressure monitoring and contrast injection rough the angiography catheter, without fusion interruption.
] A radiopaque distal tip with a level of sibility that is unsurpassed.

**ringing Concept and echnology Together**



or over 25 years, American Edwards has een merging promising concepts in critical care medicine, with the technology to make those ideas tangible.

From heart valve replacement, to hemodynamic monitoring, to sub-selective coronary infusion...helping you improve the quality of life is what we're all about.

# Exercise 2-Dimensional Echocardiography

## Quantitation of Left Ventricular Performance in Patients With Severe Angina Pectoris

MICHAEL H. CRAWFORD, MD, K. WRAY AMON, BS, and WILLIAM S. VANCE, MD

**To assess the feasibility and reproducibility of exercise 2-dimensional (2-D) echocardiography for quantitating left ventricular size and performance, 25 patients with angina pectoris due to severe coronary artery disease and 10 normal subjects were studied before and after the administration of nitroglycerin. In 18 (72%) of the 25 patients, suitable biapical 2-D echocardiograms for quantitative analysis were recorded during upright bicycle exercise. Left ventricular volume (Simpson's rule), ejection fraction (EF), and wall motion score (10 segments graded 0 to 3, normal to dyskinetic) were measured at rest, and at peak exercise (control), 30 minutes later at rest, after nitroglycerin at rest, and at peak exercise. EF increased during control exercise in the normal subjects from 57 ± 16 to 71 ± 22% ($p < 0.01$), but was unchanged in the patients during exercise before nitroglycerin. In 7 patients (39%), marked increases in EF (>0.05 units) during exercise occurred after nitroglycerin administration. The wall motion score increased significantly in the patients during control exercise, from 2.6 ± 3.4 to 5.6 ± 4.5, but was less at maximal exercise after nitroglycerin (3.4 ± 4.0, $p < 0.001$). Intra- and interobserver variability in these measurements was acceptable. Thus, quantitation of left ventricular performance during exercise by biapical 2-D echocardiography can be accomplished in a high proportion of patients with coronary artery disease (CAD) and can be used to assess the effects of therapeutic interventions.**

Recently, there has been considerable interest in echocardiography during exercise. We and others have demonstrated that the use of M-mode echocardiography during exercise to evaluate changes in left ventricular size and performance in response to various types of exercise[1] and cardiac drugs.[2,3] Mason et al[4] have detected new wall motion abnormalities on M-mode echocardiography during supine bicycle exercise in a select group of patients with CAD. Wann et al[5] applied an early 30° sector scanner in a similar group of patients to identify exercise-induced wall motion abnormalities, which corresponded in some of the patients to areas of decreased perfusion on exercise thallium scans. However, they noted a 25% incidence of falsely negative exercise echo studies, despite significant CAD. Morganroth et al[6] studied a larger group of patients with wide-angle 2-D echocardiography; this group often exhibited wall motion abnormalities during supine bicycle

From the Department of Medicine, Division of Cardiology, University of Texas Health Science Center and Veterans Administration Hospital, San Antonio, Texas. Supported in part by the Veterans Administration. Manuscript received May 3, 1982; revised manuscript received July 27, 1982, accepted July 30, 1982.

Address for reprints: Michael H. Crawford, MD, Department of Medicine, University of Texas Health Science Center, 7703 Floyd Curl Drive, San Antonio, Texas 78284.

exercise, but the incidence of false-negative studies was 52%.

In studies employing exercise radionuclide angiography, the addition of quantitating global left ventricular performance has been additive to qualitative wall motion analysis and has improved sensitivity for detecting CAD.[7] We recently developed a technique for determining left ventricular volume and EF from biapical 2-D echocardiography and the EF measurements compared favorably to those by radionuclide angiography.[8] Accordingly, the purpose of this study was to evaluate the feasibility and reproducibility of determining left ventricular performance during upright bicycle exercise in patients with severe CAD and to document changes produced by the administration of nitroglycerin. Also, the observations in patients with CAD were compared to those in a group of normal subjects.

## Methods

**Subjects:** The patient population consisted of 25 men (mean age 59 years) who were evaluated because of severe angina pectoris. All were in functional class III and had a Bruce protocol treadmill exercise test positive for ≥0.1 mV of flat or downsloping electrocardiographic S-T segment depression and angina pectoris at <7 minutes of exercise. Eighteen (72%) were found to have 2-D echocardiograms suitable for analysis during upright bicycle exercise. Left heart catheterization with left ventriculography and selective coronary cineangiography were performed within 1 week of the exercise echocardiographic study. All patients had at least 1 vessel with ≥90% luminal diameter narrowing. Eleven patients had ≥50% narrowing of 3 vessels, 6 had double-vessel disease, and 1 had single-vessel disease. Thirteen of the 18 were taking propranolol and isosorbide dinitrate. Five were also taking digoxin. Due to the severity of these patients' angina, only the isosorbide dinitrate was discontinued 12 hours before the study. Ten normal men (mean age 26 years) without evidence of cardiac or other chronic disease by history, physical examination, electrocardiography, or echocardiography served as a control group.

**Study procedure:** A 2-D echocardiogram, 2-lead electrocardiogram, and blood pressure by cuff sphygmomanometer were obtained during the study as follows. First, measurements were made with the subjects at rest, sitting on the exercise bicycle. Then, the measures were repeated at each minute during symptom-limited graded upright bicycle exercise, performed on a braked bicycle ergometer with an initial work load of 150 kpm/min for 3 minutes, which was increased by 150 kpm/min at 3-minute intervals. Exercise was discontinued for 30 to 40 minutes and repeat resting measures were obtained. Then, 0.4 mg of nitroglycerin was administered sublingually and after ≥10 mm Hg decrease in systolic blood pressure, rest measurements were repeated, followed immediately by repeat exercise testing using the same exercise protocol.

**Echocardiographic technique:** Two-dimensional echocardiography was performed with a handheld transducer using our previously described upright exercise technique.[9] All subjects were studied with the apical 4-chamber and apical long-axis views using a phased array Varian V-3000 or V-3400 echocardiograph. Images were stored on 0.5-inch videotape for later playback and analysis using the Varian, microprocessor-controlled video light pen system. Measurements of end-diastolic and end-systolic volumes were made during expiration on stop-frame images of the biapical orthogonal views using Simpson's rule. This technique for estimating left ventricular size previously has been shown to consistently underestimate volume when compared with biplane cineangiography, but correlates well even in patients with marked wall motion abnormalities. Since each subject served as his own control, the volumes were not corrected by regression formulas. EF was calculated in the standard fashion and was shown in our previous study to accurately estimate biplane cineangiographic and radionuclide angiographic values.[8] An example of 1 apical view at rest and during exercise from 1 of the normal subjects is shown in Figure 1. Although endocardium can be appreciated in these stop-frame images, it must be realized that photographs of a video stop frame reproduced in a journal contain much less detail than is available on the original video recording.

Left ventricular wall motion was evaluated by 2 independent observers for 5 segments of equal arc length in each apical view (total 10 segments per subject) and scored as follows: 0 = normal, 1 = hypokinetic, 2 = akinetic, and 3 = dyskinetic as compared with the normal subject's wall motion for these same segments. The 2 observers never disagreed by more than 1 grade, and most disagreements involved the hypokinetic and normal grades. Therefore, the average score between the 2 observers was used in the final analysis.

**Statistical analysis:** Five measurement points were analyzed in each individual: initial resting measures, peak measures during the first exercise, second resting measures, resting measures after nitroglycerin administration, and peak measures during the postnitroglycerin exercise. A 2-way analysis of variance for repeated measures was employed to test for any significant differences between these 5 measurement times in all but 2 of the variables (wall motion and blood pressure). Individual mean differences were sought by the Student Newman-Keul's test based on the range. Wall motion score and blood pressure were found to have inhomogeneous variances, so a Friedman's test was used to assess significant changes in the 5 measurement points, and individual mean differences were sought by the Wilcoxon rank-sum method. The data for each measurement time are expressed as mean ± 1 standard deviation.

## Results

**Heart rate:** In the patients, the first and second resting measurements did not differ (65 ± 8 versus 60 ± 13 beats/min), but the resting value after nitroglycerin administration was significantly increased (78 ± 17 beats/min, $p < 0.01$). Heart rate increased during exercise, both before and after nitroglycerin, but there was no significant difference between the peak exercise values (103 ± 19 versus 105 ± 23 beats/min). Similar results were observed in the normal subjects, except that the exercise heart rates were faster.

**Systolic blood pressure:** There was no difference between the first and second resting measures in the patients (130 ± 13 versus 127 ± 10 mm Hg), but the resting value after nitroglycerin administration was significantly lower (114 ± 10 mm Hg, $p < 0.001$). At peak exercise systolic blood pressure had increased, but there was no significant difference in the values before and after nitroglycerin (149 ± 26 versus 157 ± 22 mm Hg). Similar results were observed in the normal subjects.

**End-diastolic volume:** In the patients, the first and second resting measurements of end-diastolic volume

did not differ (both 86 ± 32 ml), but the resting value after receiving nitroglycerin was significantly decreased (71 ± 30 ml, $p < 0.01$). The values at peak exercise were somewhat higher than the resting values, both before and after nitroglycerin, but did not differ significantly. By contrast, in the normal subjects, the values at peak exercise were significantly higher than the corresponding values at rest (106 ± 31 versus 88 ± 28 ml, $p < 0.05$) before and after nitroglycerin (97 ± 44 versus 65 ± 22 ml, $p < 0.05$). Also, peak exercise end-diastolic volume was significantly lower after nitroglycerin administration (97 ± 44 versus 106 ± 31 ml, $p < 0.05$).

**Ejection fraction:** There was no significant difference in EF in the patients at any point in the study. However, 7 patients exhibited a marked increase in EF (>0.05 units) during exercise after nitroglycerin as compared with the control exercise values (Fig. 2). EF increased markedly in the normal subjects with exercise from 57 ± 16% to 71 ± 22% ($p < 0.01$) before administration of nitroglycerin and from 58 ± 22% to 74 ± 16% ($p < 0.01$) after nitroglycerin (Fig. 3), but the postnitroglycerin values did not differ from the corresponding control values.

**Wall motion score:** The wall motion abnormality score in the patients did not differ in the 2 resting studies before nitroglycerin (2.6 ± 3.4 versus 2.6 ± 3.7). After nitroglycerin it was lower, but not significantly so (1.7 ± 2.6). The wall motion abnormality score increased at maximal exercise as compared with rest before nitroglycerin (5.6 ± 4.5 versus 2.6 ± 3.4, $p < 0.001$) and after nitroglycerin (3.4 ± 4.0 versus 1.7 ± 2.6, $p < 0.005$). However, the value at peak exercise after nitroglycerin was significantly lower than that before nitroglycerin (3.4 ± 4.0 versus 5.6 ± 4.5, $p < 0.001$) (Fig. 4). The normal subjects showed no wall motion abnormalities at rest or during exercise.

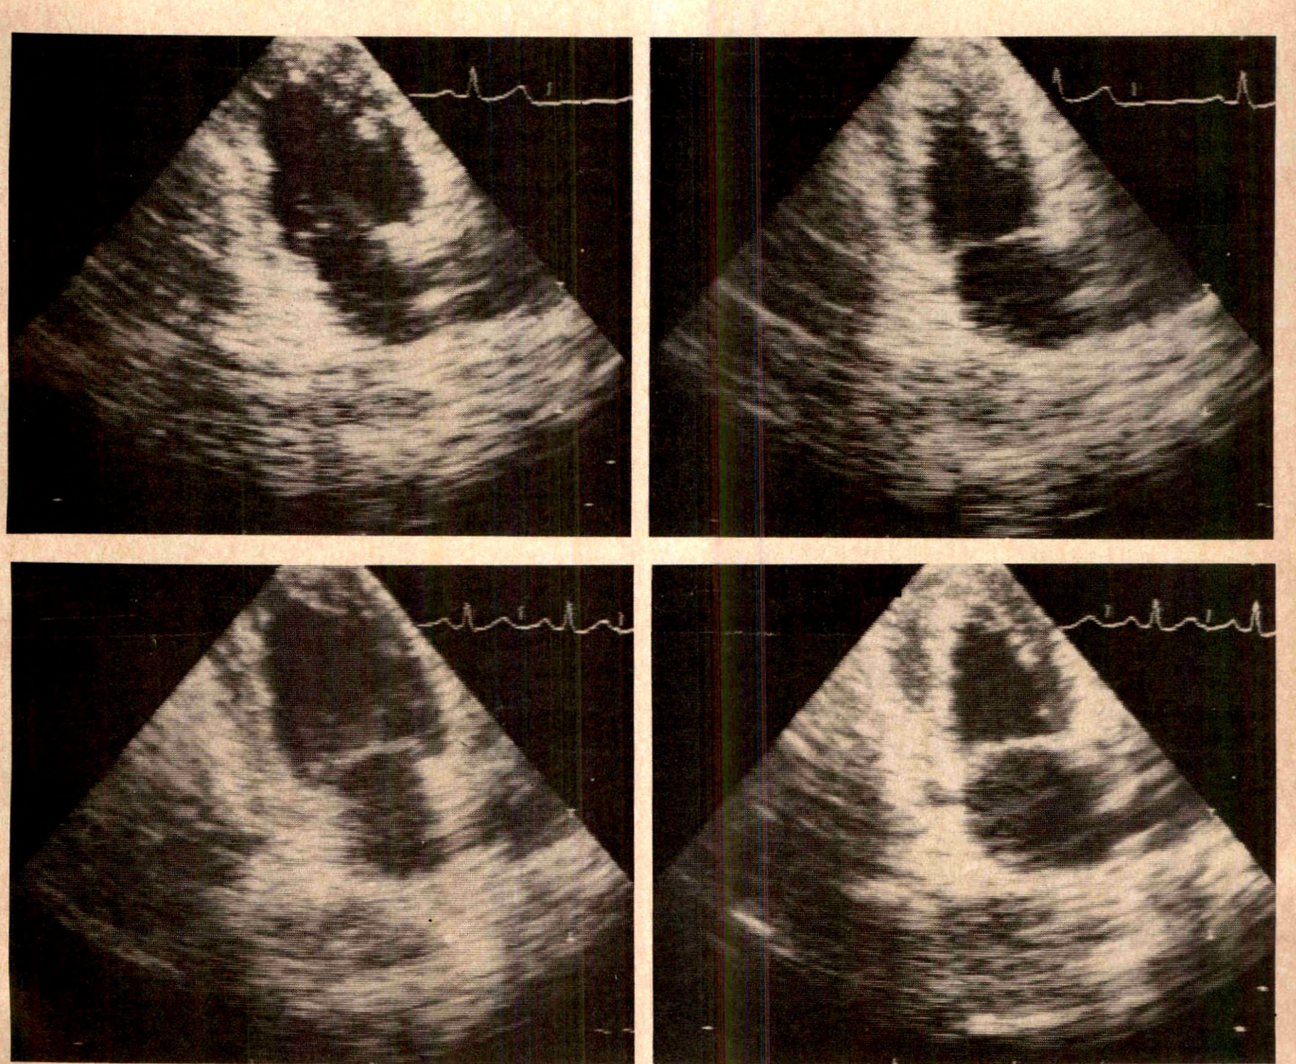

**FIGURE 1.** Apical long-axis view from a normal subject. **Top left,** end-diastole at rest; end-diastolic volume = 106 ml. **Top right,** end-systole at rest; EF = 51%. **Bottom left,** end-diastole during peak exercise; end-diastolic volume is larger than at rest at 140 ml. **Bottom right,** end-systole at peak exercise. Note the smaller end-systolic volume as compared with at rest, resulting in a higher EF of 78%.

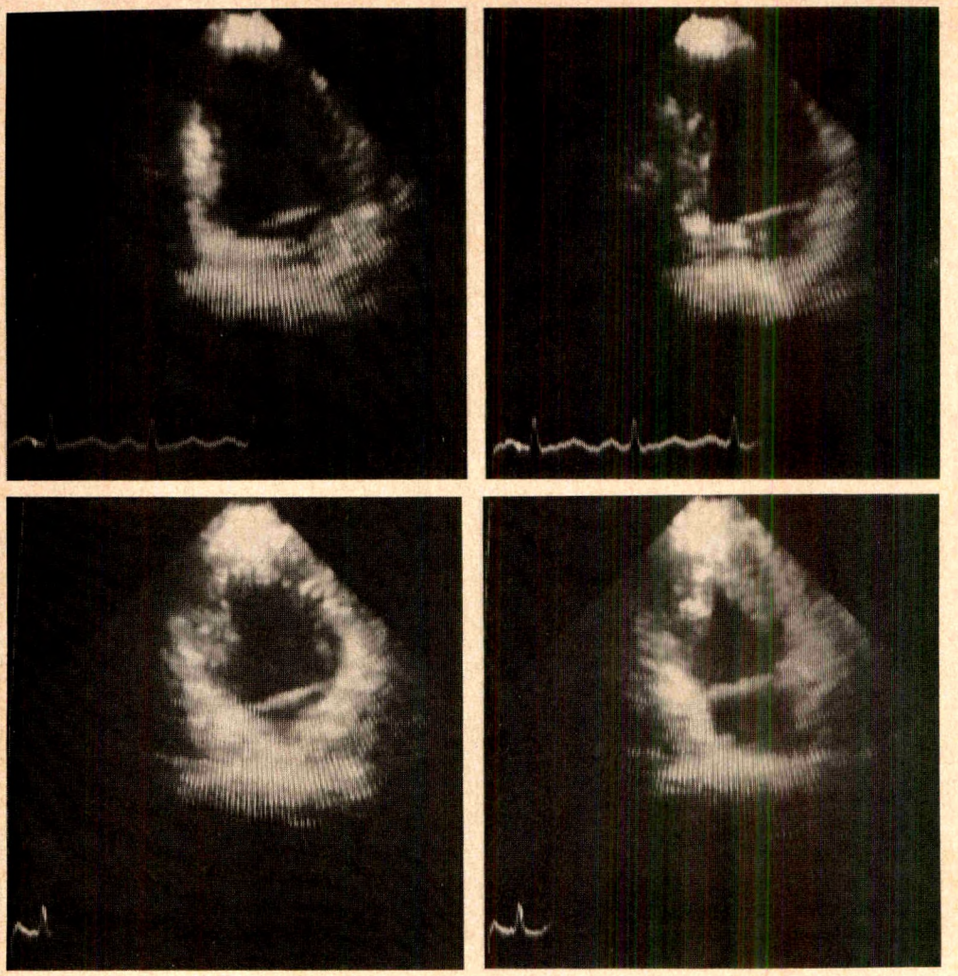

**FIGURE 2.** Apical long-axis echocardiograms during exercise from 1 patient in whom wall motion and EF improved after nitroglycerin. **Top left,** end-diastole at the peak of control exercise; end-diastolic volume = 121 ml. **Top right,** end-systole from the same cardiac cycle. Note the poor contractile effort, especially at the apex. EF = 13%, a decrease from 30% at rest. **Bottom left,** end-diastole at peak exercise after nitroglycerin administration. The end-diastolic volume has decreased to 108 ml. **Bottom right,** end-systole from the same cardiac cycle. Note the improvement in apical contraction. The EF has increased, as compared with control exercise, to 22%.

**Reproducibility:** The 2 resting control studies before and after the first exercise test made it possible to evaluate the individual reproducibility of the echo measurements from time to time by the same observer (intraobserver). The mean difference in end-diastolic volume was 8 ml, or 9% of the initial value. Wall motion classification was discordant at 9 (5%) of 170 sites, but never greater than 1 gradation and never concerning dyskinetic segments. Also, the maximal number of discordant sites in any patient was 2. In addition, because of the subjective nature of wall motion classification, 2 individuals reviewed all the studies indepen-

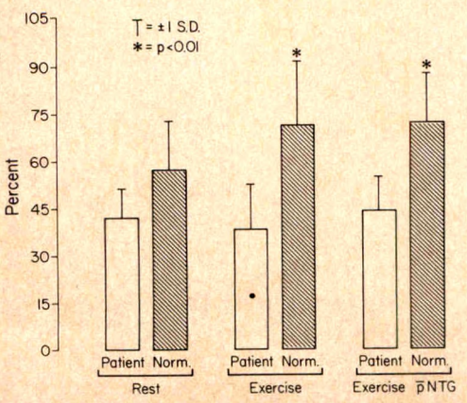

**FIGURE 3.** Mean EF at rest, during the peak of control exercise, and exercise after nitroglycerin (p̄NTG) in the patients and normal (Norm.) subjects. (See text for details.)

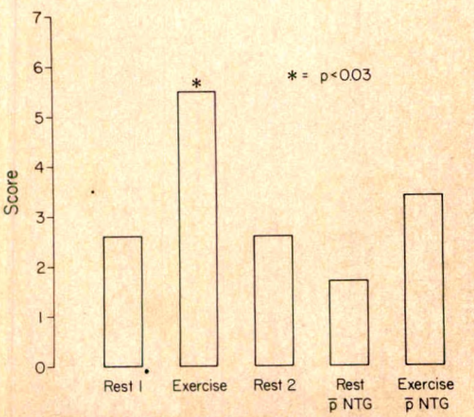

**FIGURE 4.** Mean wall motion score is depicted for each stage of the study. p̄NTG = postnitroglycerin.

dently (interobserver) and the mean number of discordant segment classification was 14% (23 of 170 segments). Again, the differences were never more than 1 grade and the exercise studies were as consistent as the resting ones. Furthermore, 4 patients consented to repeat the entire protocol in order to evaluate the intraobserver reproducibility of the echo measurements during exercise. The mean difference in end-diastolic volume on the first exercise test (control) was 8 ml and on the second (after nitroglycerin) was 4 ml. The mean difference in EF was 4% and 3%, respectively.

## Discussion

Our results demonstrate that biapical 2-D echocardiograms of sufficient quality for quantitating left ventricular global performance can be obtained during upright bicycle exercise in many patients with CAD. Our success rate of 72% for quantitative and qualitative analysis during upright exercise is similar to that of 71% by Wann et al[5] and 78% by Morganroth et al[6] for the qualitative assessment of wall motion abnormalities alone during supine exercise. Also, the 80% success rate reported by Maurer and Nanda[10] for the qualitative analysis of echoes recorded with the patient in the supine position immediately after treadmill exercise is not much better. In a previous study, we demonstrated that resting wall motion assessment by biapical 2-D echocardiography compared favorably with that by biplane cineangiography and radionuclide angiography.[11] Also, the interobserver agreement in qualitative wall motion analysis of 86% is similar to that of 95% reported by Morganroth et al[6] during supine exercise. In addition, the interobserver variability in the quantitative 2-D echocardiographic measurements of left ventricular performance at rest and on exercise are comparable to those reported for measuring left ventricular EF during exercise by radionuclide angiography.[12]

Our exercise EF results in the patients with CAD exhibit more variability than those reported in other studies using radionuclide angiographic techniques. Most studies using radionuclide angiography have shown a decrease in exercise EF, especially if the patient develops angina pectoris, as did all our patients.[13] Patients with CAD who do not have angina have been reported to show no change in EF.[14] We observed no significant difference in mean EF during exercise as compared with during rest, despite the fact that the value decreased markedly in 11 patients, because 3 showed no change and EF increased in 4. Although most radionuclide studies show an occasional patient whose EF increases with exercise, our group was unusual in that one fifth showed this response. Technical differences may explain this discrepancy. Since exercise radionuclide angiography uses only 1 view, the biplane capabilities of our 2-D echo approach may detect compensatory hyperactivity in normal segments during exercise not viewed in only 1 plane. Also, in some radionuclide studies in which first-transit techniques are used, resting studies were obtained soon after exercise—a time at which left ventricular function may be improved.[12]

EF was unchanged by nitroglycerin at rest and on exercise in both groups. The EF results in normal subjects are similar to those reported in others using radionuclide techniques,[15,16] but some studies in CAD patients have shown an improvement in exercise EF following nitrates.[16] However, these radionuclide studies used supine exercise, the results of which may differ from upright exercise, which we used. Also, these differences may represent patient population variations, since in our patients with severe CAD, only 7 showed a significant improvement in exercise EF after the administration of nitroglycerin.

The clinical utility of biapical 2-D exercise echocardiography remains in question. Although the apical approach allows for the visualization of the entire left ventricle in 2 orthogonal planes, a large area of endocardium is parallel to the sound beam. Poor endocardial images was the major limitation in the study, since our upright exercise echo technique minimizes problems with patient movement and all measurements were made during expiration when the heart is relatively stationary in the chest. By contrast, the almost 100% success rate of radionuclide angiography makes it an attractive procedure. However, echocardiographic equipment is less expensive and may be more readily available, and the lack of any potentially harmful radiation exposure makes serial studies before and after pharmacologic interventions feasible.

We believe that the addition of a quantitative assessment of left ventricular global performance, as we have described, will enhance the value of exercise echocardiography. The current study, however, was not designed specifically to assess this hypothesis, but rather to establish the feasibility and reproducibility of acquiring studies suitable for quantitative analysis. If the experience with radionuclide studies during exercise is shown to be applicable to echocardiography, then the sensitivity for detecting CAD will be increased by assessing global left ventricular performance. Also, an assessment of left ventricular function during exercise is valuable in studying symptoms in patients with known CAD, as is demonstrated in our study. All of our patients had angina and poor treadmill exercise tolerance, but in only 11 was the reduced exercise capacity due to a deterioration in left ventricular performance. In addition, nitrate administration improved exercise performance in 6 of these 11. Therefore, if further technological improvements increase the incidence of high quality studies, exercise biapical 2-D echocardiography could become an important addition to the evaluation of patients with suspected or overt CAD.

# Importance of Complete Revascularization in Performance Of the Coronary Bypass Operation

ELLIS L. JONES, MD, JOE M. CRAVER, MD, ROBERT A. GUYTON, MD, DAVID K. BONE, MD, CHARLES R. HATCHER, Jr., MD, and NORMAN RIECHWALD, PA

**Cardiac Data Bank records of 1,238 patients with triple-vessel disease (≥50% diameter reduction) who had undergone coronary bypass surgery were reviewed and divided into 2 groups depending on whether complete (n = 773) or incomplete (n = 465) revascularization had been accomplished. Patients with complete revascularization had a higher incidence of a normal preoperative electrocardiogram than did patients with incomplete revascularization (23 versus 14%, respectively, p <0.0001). The ejection fraction for both completely and incompletely revascularized patients was good (m = 0.60 and 0.57, respectively). The mean number of grafts per patient for the 2 groups was 3.8 and 2.6 (p <0.0001). There was no significant difference between the 2 groups with regard to postoperative inotropic requirements (8 and 7%), ventricular arrhythmias (1.8 and <1%), necessity for intraaortic balloon pumping (1.6 and 1.5%), hospital mortality (1.2 and 2.8%), or myocardial infarction (4.3 and 4.8%). Survival at 5 years was significantly greater (p <0.001) in patients with complete (88.5%) than in those with incomplete revascularization (83.5%). Reemployment occurred more often in patients with complete (52%) than in those with incomplete revascularization (40%) (p <0.001), and more patients were free of angina after complete (70%) than after incomplete revascularization (58%) (p <0.0005). Long-term survival appeared to be mediated primarily through improved revascularization rather than through differences in left ventricular function.**

A number of factors in the development of the coronary bypass operation have served to reduce hospital mortality, improve qualitative results, and increase long-term survival. One of these factors has been the technical ability to bypass smaller and often more diseased arteries and offer more "complete" revascularization to a progressively larger patient population. However, a comprehensive look at the effects of complete revascularization have only briefly been alluded to in the past.[1–5] Furthermore, clinical factors important in determining which patients will be candidates for complete revascularization have been infrequently discussed.

The purpose of this retrospective study is 2-fold: first, to define those clinical descriptors which influence satisfactory or unsatisfactory revascularization, and second, to define the differences in hospital mortality, perioperative complications, symptomatic improvement, and long-term survival effected by the completeness of the revascularization process.

## Methods

Cardiac Data Bank records of 1,238 patients who underwent isolated coronary bypass surgery from January 1973 through March 1982 were retrospectively analyzed. All patients selected for this study had triple-vessel disease with ≥50% reduction in luminal diameter of the left anterior descending, the circumflex or its major branches, and the right coronary artery. Patients were classified into 1 of 2 groups on the basis of whether complete or incomplete revascularization had been performed. Complete revascularization was accomplished if any artery to those regions usually supplied by the left anterior descending, the circumflex, and the right coronary artery was bypassed. Inability to perform bypass grafting to arteries supplying 1 or more of these 3 areas was considered incomplete revascularization. For instance, when a lateral circumflex artery was bypassed (but not an obstructed posterolateral marginal branch) or when the left anterior descending artery

was bypassed but a significantly obstructed diagonal branch remained ungrafted, then complete revascularization was said to have been accomplished since both the obtuse margin of the heart and anterior wall, respectively, received grafts to the area at risk.

Patients excluded from analysis were those with previous coronary bypass surgery, left ventricular aneurysm, left dominant circulation, combined operative procedures, and left main coronary artery disease, or patients who had had coronary bypass surgery within 30 days of myocardial infarction.

Systemic hypertension was defined as blood pressure elevation sufficiently severe to require antihypertensive medication at some time before cardiac catheterization. Congestive heart failure was said to be present if there was a history of dyspnea or orthopnea or if the patient had objective evidence of alveolar or interstitial pulmonary edema before catheterization. Unstable angina was defined according to the criteria of Logue et al[6] and did not require the presence of electrocardiographic ST-T changes. Pressure of cardiomegaly was determined by excessive enlargement of the cardiac silhouette on admission chest radiography.

Evaluation of left ventricular function was performed by angiographic analysis of left ventricular regional wall motion, ejection fraction (right anterior oblique), and resting end-diastolic pressure. Normal and mild impairment of segmental wall motion were treated as normal. Moderate and severe impairment were classified as abnormal.

**Operative technique:** A disposable bubble oxygenator and systemic hypothermia to 28°C nasopharangeal were used in all patients. Since 1975, patients have received propranolol therapy up to the time of surgery. Cold (4°C) potassium or potassium hyperosmolar cardioplegia has also been used since then for myocardial preservation (hyperkalemic solution: potassium chloride solution [20 mEq/liter] buffered to pH 7.40). Hyperkalemic-hyperosmolar solution (concentration in mEq/liter): potassium, 28; the bicarbonate radical, 9.3; sodium, 95.7; dextrose (50%), 3.2 ml; mannitol (15%), 200 ml with sterile water to 1,000 ml; pH 8.1; osmol = 415 mosmol at room temperature. Left ventricular filling pressure, cardiac output, and peripheral resistance are routinely monitored with a Swan-Ganz catheter. Since 1976, an uninterrupted cross-

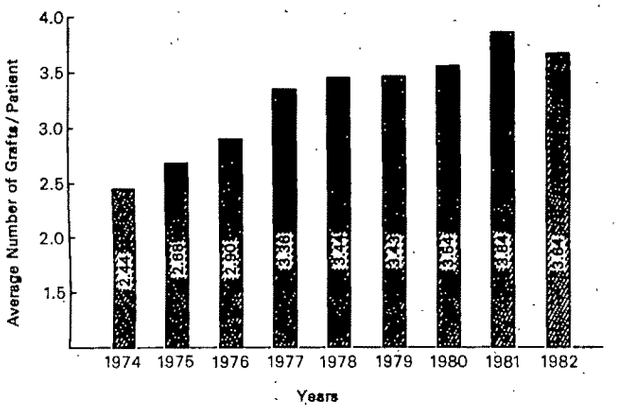

**FIGURE 1.** Relation between number of grafts per patient and year of surgery.

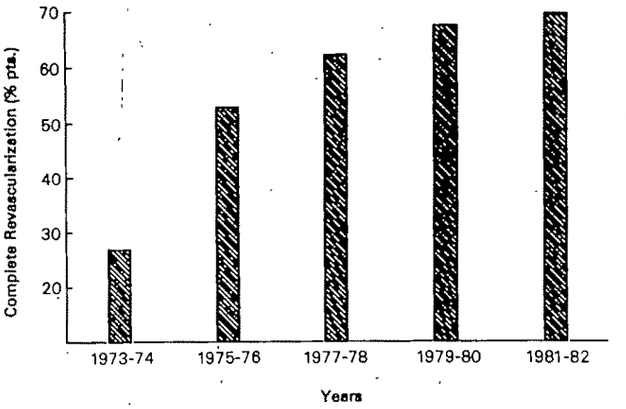

**FIGURE 2.** Frequency of complete revascularization as a function of year of surgery.

clamp technique has been used to perform all distal anastomoses. Coronary endarterectomy was not used in any patient.

**Perioperative data analysis:** Patients were classified as inotropic-dependent if they required an intravenous infusion of drugs to maintain blood pressure or adequate cardiac output after cardiopulmonary bypass. Perioperative infarction was said to have occurred if there was development of electrocardiographic new Q waves of ≥0.04-second duration. Hospital or operative mortality included any death occurring in the hospital from complications directly attributable to the operation. Survival curves were calculated by the actuarial method according to Cutter and Ederer[7] with time zero being the date of operation. Statistical differences between patient groups were determined by chi-square analysis. All survival curves depict gross and not cardiac survival.

Because of the voluminous amount of data relating to such a large patient population, the number of patients involved in any given comparison frequently varied as a function of missing data for the variables involved. Missing data were usually attributable to clinical evaluation and cardiac catheterization performed outside our medical facility.

## Results

The total series included 773 patients with complete and 465 with incomplete revascularization. The mean age of both groups of patients was 56 years, and 88% and 87% of the groups, respectively, were male.

There was no difference in the preoperative anginal pattern in the 2 groups of patients, with approximately 67% of the patients in each category having unstable angina pectoris. Approximately 50% of the patients in each category had pain at rest. The duration of angina for both groups of patients was 41 months. Risk factors such as hypertension and a history of family members aged <55 years with a past coronary event were a significant finding in both groups of patients. However, there was no statistically significant difference in the incidence of these risk factors between the 2 groups (Table I).

A higher percentage of patients with complete revascularization had a normal preoperative electrocardiogram than of those with incomplete revascularization, and the difference was statistically significant. The incidence of preoperative anterior transmural infarction in patients with incomplete revascularization was slightly higher than in those with complete revascularization. There was no significant difference in the incidence of cardiomegaly between the 2 groups (Table II).

**Catheterization profile: left ventricular function:** Angiographic analysis of left ventricular wall motion revealed that a significantly higher percentage of patients in the complete revascularization group had normal or minimally depressed contraction pattern, with a significantly higher incidence of 1 or more akinetic left ventricular wall segments in the incomplete revascularization group. There was no difference in the percentage of patients having increased resting left ventricular end-diastolic pressure (Table III). The mean ejection fraction was 0.60 for patients with complete revascularization and 0.57 for those with incomplete revascularization ($p < 0.001$). Although the difference achieved statistical significance, both values were well within normal range and the difference was not clinically significant. However, the percentage of patients with an ejection fraction <0.40 was significantly higher in the incomplete than in the complete revascularization group (10%, 44 of 436 patients; and 5.8%, 41 of 712 patients, respectively; $p < 0.005$). The incidence of mitral regurgitation (mild to moderate) was not significantly different in the 2 groups, averaging 4% (27 of 705) for the completely revascularized group and 4.7% (17 of 433) for the incompletely revascularized group.

**Operative profile:** The mean number of grafts performed per patient was significantly higher in patients with complete than in those with incomplete revascularization. In addition, the mean aortic cross-clamp time per graft was higher in those with incomplete revascularization. The greater number of grafts in the completely revascularized group was largely accomplished by using sequential grafting techniques or by taking advantage of natural Y-graft branches (Table IV). Figure 1 shows the average number of grafts per-

NS = not significant.

formed per patient in the years 1974 through 1982. Figure 2 shows the progressive increase in the percentage of patients receiving total revascularization throughout the years of the study. Hospital mortality by year of surgery is shown in Table V.

**Perioperative complications:** Surprisingly, there was no difference in the incidence of inotropic requirements, ventricular arrhythmias, or intraaortic balloon pumping after coronary bypass in patients with complete and incomplete revascularization. Although hospital mortality was higher in patients with incomplete than in patients with complete revascularization (2.8 versus 1.2%, respectively) this difference did not achieve statistical significance. The incidence of perioperative electrocardiographic new Q waves was slightly over 4% for the 2 groups of patients (Table VI).

**Follow-up:** Approximately 80% of patients in both groups were employed before coronary bypass surgery. However, 52% of the patients with complete revascularization were working at the time of follow-up, compared with only 40% of those with incomplete revascularization; this difference was highly statistically significant.

Of the patients with angina before surgery who had complete revascularization, a higher number were free of angina at follow-up compared with those with incomplete revascularization (70 and 58%, respectively) (Table VII). The average interval between surgery and follow-up evaluation was 22 months for those with complete and 26 months for those with incomplete revascularization.

The 5-year survival rates for patient with complete and incomplete revascularization were 88.5 and 83.5%, respectively (Fig. 3); this difference was significant ($p < 0.001$).

## Discussion

As noted by others,[1,2] the concept of complete revascularization is difficult to communicate, and therefore a regional myocardial definition has been substituted for the traditional one which required a bypass graft to every significantly obstructed coronary artery. It was felt that more importance should be given to the ability or inability to revascularize an entire region of myocardium (anterior wall, obtuse margin, or inferior surface). Clinical data obtained from patients in whom it is not possible to revascularize an entire cardiac segment should demonstrate a difference in early and late clinical results from those in whom all regions of the myocardium have been grafted. Patient with complete revascularization as defined by the traditional concept, in which every significantly obstructed artery must be bypassed, are not likely to demonstrate a significant clinical difference from those with incomplete revascularization when the only operative difference might be an unbypassed branch vessel such as the left anterior descending diagonal, a left ventricular branch of the right coronary system, or only 1 of several obtuse marginal arteries.

Classification of patients into revascularization groups at the time of surgery rather than at postoperative catheterization as reported in previous studies[3–5] was done in order to evaluate preoperative variables as predictors of future clinical performance and to obtain a sample size large enough for meaningful statistical analysis. In our patient population, only 8.7% of the

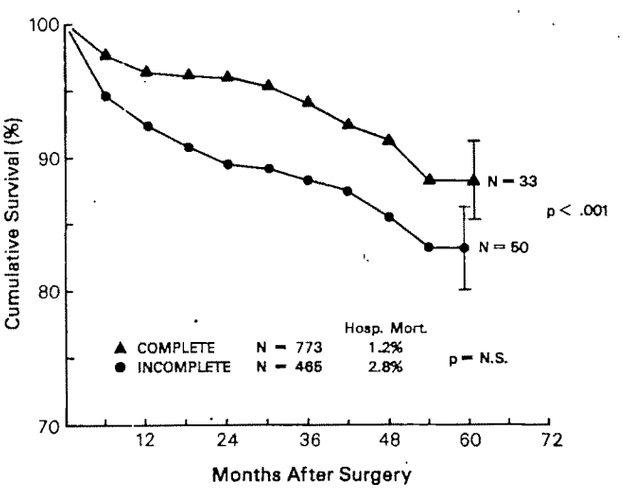

**FIGURE 3.** Actuarial survival curve (all deaths) for patients with complete and incomplete revascularization. Hosp. Mort. = hospital mortality; N.S. = not significant.

completely and 17.4% of the incompletely revascularized group had recatheterization data available for analysis. The fact that the major indication for recatheterization was recurrent ischemic symptoms precluded any meaningful conclusions based upon arteriographic studies; for this reason, such an analysis of postoperative catheterization information would have been biased and misleading.

Only patients with triple-vessel disease were included in this report. Previously reported series[1,4] included many patients with single- and double-vessel disease, and the heterogeneity of these patient populations explains many of the differences in results in the present series and others.

Incomplete revascularization has usually been attributed to myocardial fibrosis, minute vessel size, or diffuse atherosclerosis.[1] Even though the number of grafts per patients and the percentage of patients with complete revascularization has increased progressively over the years, reduction in hospital mortality is not necessarily a direct effect of these 2 factors as was previously suggested.[8] Decreases in hospital mortality and perioperative complications over the years are probably related more to improved anesthetic and surgical techniques, myocardial preservation, reduced intraoperative catastrophes (such as aortic dissection and massive intraoperative infarction), and better pharmacologic management in the postoperative period than to completeness of revascularization. This finding differs from those in previous studies.[2]

The lack of correlation between electrocardiographic evidence of postoperative myocardial damage and inability to revascularize an entire segment of myocardium suggests that perioperative infarction is related more to reperfusion injury in the area supplied by the grafted artery than to insufficient blood flow through the native circulation at the conclusion of the operative procedure.[9]

The relation between completeness of revascularization and long-term survival was found to differ from the effect of complete revascularization on hospital mortality. In the present study as well as previous reports,[1,2] 5-year survival is significantly improved in patients with complete revascularization. However, this finding differs from observations in patients assigned to revascularization status according to graft patency and freedom from new disease 1 year after surgery. When revascularization status was so defined, no difference in long-term survival could be demonstrated in patients with complete or incomplete revascularization.[3]

Several studies[2,10,11] have noted that late postoperative mortality was significantly elevated in patients with angiographic segmental wall motion abnormalities. This raises the question of whether improved long-term survival after complete revascularization in this group might be mediated primarily through better left ventricular function rather than through more extensive revascularization. As demonstrated in the present study, patients with incomplete revascularization had a high incidence of angiographic segmental wall motion abnormalities, which were probably a result of significant ventricular fibrosis and decreased segmental blood supply. However, other than depression of segmental wall motion, there was no clinical difference in left ventricular function (mean ejection fraction, left ventricular end-diastolic pressure) in patients with complete and incomplete revascularization, and therefore the mechanism of increased long-term survival was probably mediated through better revascularization. Loop et al[1] reported that patients with complete revascularization have a 5-year survival rate of approximately 94%, compared with 88% in those with incomplete revascularization. In some series in which complete revascularization was defined at the time of postoperative cardiac catheterization, the survival rate in totally revascularized patients was even higher.[3] In our own group, the lower 5-year survival rates of 88.5 and 83.5% for completely and incompletely revascularized patients can be explained by admission into the study of only patients with triple-vessel disease.

Considerable evidence supports the fact that patients who still have symptoms after coronary bypass surgery have either incomplete revascularization, graft closure, or progression of disease distal to the anastomosis.[12,13] The important relation of complete revascularization to alleviation of angina is demonstrated in the study of Cuckingnan et al.[5] Of patients with complete revascularization (all grafts patent and no new disease), 87% had no angina at the time of follow-up. In those with incomplete revascularization but all grafts patent, absence of angina was present in only 42%, further demonstrating the adverse effect of leaving a segment or region of myocardium unrevascularized. In our own series, 70 and 58% of patients with complete and incomplete revascularization (as defined) had no angina at the time of follow-up; these results agree with the findings of previous reports.[1,14]

In the present series, a retrospective analysis of employment status for patients with either complete or incomplete revascularization revealed that equal numbers of both groups were employed before surgery. However, after coronary bypass a significantly higher proportion of the patients with complete revascularization returned to work.

In summary, the definition of complete revascularization has been made according to region of myocardium perfused rather than anatomic vessel site. Ability to achieve complete revascularization was not adversely influenced by anginal pattern, duration of angina, heart failure, hypertension, diabetes, or cardiomegaly. Complete revascularization was more likely to be achieved in patients with a normal electrocardiogram preoperatively, angiographically normal left ventricular wall motion, and ejection fraction >0.40. Perioperative complications such as reduced cardiac output, ventricular ectopy, and myocardial infarction were not significantly affected by completeness of revascularization. Although hospital mortality was slightly greater in partly revascularized patients than in those with total revascularization, this difference did not achieve statistical significance. From the present study, complete revascularization was found to significantly enhance a patient's chances of returning to employment, being

angina-free, and having better long-term survival. Although the latter may be mediated through better left ventricular function in candidates for total revascularization, the observation that mean ejection fraction and resting left ventricular end-diastolic pressure did not differ significantly in the 2 groups suggests that improved long-term survival is truly accomplished by more complete myocardial revascularization. Consideration should be given to performing as many grafts as possible with the hope that regional revascularization will be preserved should there be progression of arterial disease or later graft failure.

# Antianginal Efficacy and Improved Exercise Performance With Timolol

## Twice-Daily Beta Blockade in Ischemic Heart Disease

FRED J. HARRIS, MD, REGINALD I. LOW, MD, LINDA PAUMER, MA, EZRA A. AMSTERDAM, MD, and DEAN T. MASON, MD

**Antianginal efficacy and improved exercise performance with timolol, a new beta-adrenergic blocking agent, was assessed in 23 patients with chronic stable angina pectoris in an 11-week double-blind, placebo-controlled study. Twenty-two of the 23 subjects completed the open-label phase of this investigation (weeks 0 to 6) while receiving 10 to 30 mg of timolol twice daily to optimize exercise capacity. Weekly anginal episodes and nitroglycerin consumption declined from 8.9 ± 9.1 episodes/week and 8.1 ± 10.6 tablets/week, respectively, with placebo to 2.7 ± 5.2 episodes/week and 2.6 ± 6.0 tablets/week with optimal timolol dose ($p < 0.05$). Resting heart rate (HR) and systolic blood pressure (SBP) also decreased from 75.2 ± 14.0 beats/min and 139.1 ± 15.7 mm Hg with placebo to 55.1 ± 8.9 beats/min and 130.5 ± 15.9 mm Hg with timolol ($p < 0.05$). Peak exercise HR, peak exercise SBP, and peak exercise double product (HR × SBP) were significantly ($p < 0.05$) reduced when evaluated 12 to 13 hours after administration of timolol compared with placebo (101.5 ± 21.1 beats/min versus 193.3 ± 96.2 beats/min, 161.5 ± 26.7 mm Hg versus 175.6 + 20.8 mm Hg, and 16.6 ± 5.1 × $10^{-3}$ versus 21.7 ± 5.4 × $10^{-3}$, respectively). Exercise duration was prolonged from 263.3 ± 90.2 seconds to 330.3 ± 73.9 seconds ($p < 0.05$), while time to onset of 1 mm S-T segment depression was delayed in 15 patients from 231.8 ± 86.4 seconds to 298.7 ± 68.4 seconds ($p < 0.05$).**

**During the double-blind phase (weeks 7 to 10), 8 subjects received timolol and 11 patients received placebo. Nitroglycerin consumption at weeks 8 and 10 and anginal frequency at week 8 were unchanged compared with initial placebo treatment. Resting HR, peak exercise HR, and peak exercise double product were significantly attenuated at weeks 8 and 10 in timolol patients compared with their initial placebo exposure. However, these variables were unchanged in placebo subjects compared with their initial placebo therapy. Exercise duration was again prolonged at week 8 in timolol subjects compared with initial placebo results (315.1 ± 61.2 seconds versus 261.3 ± 68.8 seconds, $p < 0.05$), but not at week 10. Placebo patients demonstrated no difference at week 8 or 10 in exercise performance compared with initial placebo treatment.**

**Timolol twice daily, therefore, is potentially useful in some patients with angina pectoris. Other patients may, however, require a shorter dose interval for optimal angina control and maximal improvement in exercise capacity.**

Beta-adrenergic blocking agents are widely used for the treatment of angina pectoris in patients with coronary heart disease, in whom their beneficial effects on symptoms and exertional capacity have been established.[1] These effects have been reported with beta-blocking agents requiring multiple daily doses[2,3] and recently with drugs of this class which can be administered only once or twice a day to attain the desired therapeutic goal in angina.[4,5] However, due to bothersome and occasionally serious adverse effects,[6] interest continues in the identification of other beta blockers requiring only once- or twice-daily administration for treatment of angina.

Timolol maleate ([-]-L-Tert-butylamino-3-[4-morpholino-1,2,5,thiodiazol-3yloxy]-L-propranolol hydrogen maleate) is a relatively new beta-adrenergic blocking agent which has demonstrated effectiveness in the treatment of mild to moderate hypertension.[7] It has a nonselective effect on beta-adrenergic receptors, little or no membrane stabilizing activity, and no intrinsic sympathomimetic activity.[8] It has a less potent intrinsic negative inotropic effect than that of pro-

AMI = anterior myocardial infarction; AP = episode of angina pectoris; BT = best treatment, weeks 3 to 5; CABG = coronary artery bypass graft surgery; DB = double blind, weeks 8 to 10; IMI = inferior myocardial infarction; MI = myocardial infarction; P = placebo; S-T↓ = ≥1 mm S-T segment depression; 1, 2, or 3 VD = 1-, 2-, or 3-vessel coronary artery disease; + = present; − = absent.

pranolol in a dose that produces equipotent beta-adrenergic blockade.[8,9] Recently, timolol reduced long-term mortality in survivors of acute myocardial infarction.[10] Preliminary data indicate that this drug also decreases the frequency of anginal attacks and enhances exercise performance in patients with stable angina pectoris.[11,12] Little information is available, however, on the antianginal efficacy of timolol during long-term maintenance therapy.

We, therefore, evaluated the effect of 10 to 30 mg twice daily timolol upon anginal frequency and exercise capacity over a sustained time interval.

## Methods

**Patients (Table I):** The study group consisted of 23 patients (22 men and 1 woman; mean age 58.9 years, range 43 to 72) with chronic stable angina pectoris from the Cardiology Clinic, University of California, Davis, Medical Center. All subjects had exercise-induced S-T segment depression ≥1.0 mm on the electrocardiogram or significant disease defined as ≥70% narrowing of luminal diameter, or both, in at least 1 major coronary artery documented by coronary angiography. Six patients had a history of myocardial infarction only without electrocardiographic confirmation, while 5 had evidence of previous myocardial infarction on the electrocardiogram alone. Two subjects had both a history of myocardial infarction and electrocardiographic evidence of previous myocardial infarction. Seven patients had had previous coronary artery bypass graft surgery but were receiving treatment for recurrent angina. Nine had significant 3-vessel coronary artery disease, 6 had 2-vessel disease, and 4 had 1-vessel disease. Three patients did not undergo cardiac catheterization and coronary angiography but had exertional chest pain with exercise-induced S-T segment depression. One subject with angina and exercise-induced S-T segment depression (Patient 12) underwent coronary angiography for increasing chest pain after completion of the investigation. She had normal coronary arteries with normal left ventricular function and was therefore excluded from the data analysis.

Twenty-two subjects completed the first 6 weeks of the study protocol while 19 patients finished the entire 11-week investigation. Of those not completing the entire 11-week protocol, 2 were lost to follow-up, 1 discontinued because of headaches and dizziness at week 6, and 1 was removed from the study due to the development of severe hypertension.

Patients were excluded for any of the following criteria: childbearing potential, age <21 years or >75 years, resting supine diastolic blood pressure >100 mm Hg despite diuretic treatment, congestive heart failure, significant cardiomegaly, myocardial infarction within the previous 6 months, valvular or congenital heart disease, second- or third-degree atrioventricular block, Wolff-Parkinson-White syndrome, tachyarrhythmias requiring therapy, cerebrovascular accident within the past year, diabetes mellitus treated with insulin or oral hypoglycemics, bronchospasm, previous adverse reaction to beta-adrenergic blockade, neoplasm, significant renal or hepatic disease, abnormal hemoglobin, abnormal platelet count, hyperthyroidism, or treatment with digitalis, antiarrhythmic drugs, anticoagulants, rauwolfia derivatives, oral contraceptives, or psychotropic drugs.

**Study design (Table II):** The study consisted of a placebo run-in period (weeks 0 to 2), followed by an open-label dose-finding period for all patients (weeks 3 to 5) in which timolol,

**TABLE II Study Design**

|---|---|
| Weeks 0–2 | Placebo |
| Weeks 3–5 | Open-label: timolol dose titration |
| Week 6 | Down-titration |
| Weeks 7–10 | Double blind: randomization to timolol or placebo treatment |
| Week 11 | Down-titration |

10 to 30 mg twice daily, was administered to determine the optimal dose. A down-titration phase (week 6) followed with randomization to double-blind treatment with placebo or timolol twice daily (weeks 7 to 10) at the previously determined optimal dose. Medication was discontinued in all subjects during week 11 of the investigation.

During this investigation, anginal frequency and nitroglycerin consumption were recorded daily in a diary by each patient. Other than the study drug, only sublingual nitroglycerin was used to treat anginal episodes. No other antianginal medication was administered during any phase of the investigation. Patients underwent symptom-limited exercise testing at weeks 0, 2, 3, 4, 5, 6, 8, and 10. All subjects were treated with 10, 20, and 30 mg of timolol twice daily during weeks 3 to 5 to define the optimal drug dose in terms of maximizing functional capacity. If these individuals achieved a resting heart rate ≤50 beats/min before receiving the last dose level, they were continued on the previous dose of the medication. During the double-blind period of the trial, subjects received either the previously determined optimal dose of timolol or the same number of placebo tablets. Complete physical examinations were performed before entry into the investigation and at week 10. Also at these times, a complete blood count was taken and serum electrolyte measurements, routine blood chemistry determinations, urinalysis, 12-lead electrocardiogram, and chest roentgenograms were obtained.

**Treadmill exercise protocol:** Exercise testing consisted of multistage symptom-limited treadmill exercise according to the standard Bruce[13] protocol. Electrocardiograph leads I, aVF, and $V_5$ were monitored continuously and a complete 12-lead electrocardiogram was recorded every 3 minutes during the test and for 6 minutes after termination of exercise. Blood pressure was determined by sphygmomanometer before exercise, every 3 minutes during exercise, and at the end of the test. Patients were exercised to an end-point of onset of angina, or to the same intensity of angina during each test. Subjects without chest pain on subsequent treadmill testing were exercised to fatigue. All patients had at least 1 prior exposure to this type of exercise before entry into the study in an attempt to negate any habituation to the treadmill. All subjects underwent exercise testing in a fasting state 12 to 13 hours after their last dose of timolol. Parameters assessed were exercise duration, resting and exercise heart rate, resting and exercise systolic blood pressure, resting and exercise double product (heart rate × systolic blood pressure × $10^{-3}$), time to onset of 1 mm S-T segment depression, and estimated myocardial oxygen consumption.

**TABLE III Open-Label Phase: Placebo Versus Optimal Timolol Treatment**

| n = 22 | Placebo | Optimal Timolol* |
|---|---|---|
| Weekly episodes angina pectoris | 8.9 ± 9.1 | 2.7 ± 5.2 |
| Nitroglycerin use (tablets/week) | 8.1 ± 10.6 | 2.6 ± 6.0 |
| Resting HR (beats/min) | 75.2 ± 14.0 | 55.1 ± 8.9 |
| Resting SBP (mm Hg) | 139.1 ± 15.7 | 130.5 ± 15.9 |
| Exercise duration (s) | 263.2 ± 90.2 | 330.3 ± 73.9 |
| Peak exercise HR (beats/min) | 193.3 ± 96.2 | 101.5 ± 21.1 |
| Peak exercise SBP (mm Hg) | 175.6 ± 20.8 | 161.5 ± 26.7 |
| Peak exercise double product (HR × SBP × $10^{-3}$) | 21.7 ± 5.4 | 16.6 ± 5.1 |
| Time to onset 1 mm S-T↓ (s) (n = 15) | 231.8 ± 86.4 | 298.7 ± 69.9 |

* $p < 0.05$ for all of these measurements. S-T↓ = S-T segment depression.

**Statistical analysis:** Student's $t$ test for paired and nonpaired data was used to determine the statistical significance of differences in group mean data. Group data are presented as mean ± 1 standard deviation of the mean.

## Results

Twenty-three patients completed the open-label phase of the study. Nine received 20 mg timolol daily, 9 received 40 mg daily, and 5 received 60 mg daily as the optimal dose. Nineteen of 23 patients entered the double-blind treatment period and completed the entire investigation. These patients continued on the same timolol dose as in the open-label period except for Patients 1 and 6, whose doses were reduced because of HR <50 beats/min after randomization. Patient 12 was excluded from all data analysis.

**Open-label phase (Table III):** *Anginal frequency and nitroglycerin consumption:* Twenty-three patients with chronic angina were treated with timolol for 4 weeks. Weekly anginal frequency declined on optimal timolol dose from 8.9 ± 9.1 eposides/week with placebo to 2.7 ± 5.2 ($p < 0.05$) with timolol. Nitroglycerin consumption also was reduced from 8.1 ± 10.6 tablets/week with placebo to 2.6 ± 6.0 tablets ($p < 0.05$) with timolol.

*Resting hemodynamics and exercise variables:* Resting HR was significantly reduced by timolol from 75.2 ± 14.0 beats/min with placebo to 55.1 ± 8.9 beats/min with the drug ($p < 0.05$). Systolic blood pressure also declined from 139.1 ± 15.7 mm Hg with placebo to 130.5 ± 15.9 mm Hg with optimal timolol ($p < 0.05$). Timolol prolonged exercise capacity before the onset of angina in these patients from 263.2 ± 90.2 seconds with placebo to 330.3 ± 73.9 seconds with optimal timolol ($p < 0.05$). Concomitantly, peak exercise heart rate declined significantly, from 193.3 ± 96.2 beats/min to 101.5 ± 22.1 beats/min ($p < 0.05$) with timolol compared with placebo. Peak exercise SBP was lower with timolol than with placebo (161.5 ± 26.7 mm Hg versus 175.6 ± 20.8 mm Hg, $p < 0.05$). The double product (HR × SBP × $10^{-3}$) was also substantially reduced in these subjects, from 21.7 ± 5.4 with placebo to 16.6 ± 5.1 with timolol therapy ($p < 0.05$).

*S-T segment depression with exercise:* Fifteen (68%) of 22 patients manifested exercise-induced S-T segment depression while receiving both placebo and optimal dose timolol. The appearance of 1 mm S-T segment depression was delayed from 231.8 ± 86.4 seconds with placebo to 298.7 ± 69.9 seconds with timolol ($p < 0.01$). Five subjects had evidence of myocardial ischemia with placebo but not with optimal timolol. Three of these patients exercised to a higher work load while receiving timolol. Two demonstrated no S-T segment change in either period.

**Double-blind phase (Table IV):** Eighteen patients completed the double-blind phase of this investigation. Eight were randomized to timolol treatment at their previous open-label dose while 10 received placebo for this period.

*Anginal frequency and nitroglycerin consumption:* Anginal episodes did not decline at week 8 in timolol subjects (6.5 ± 8.4 episodes/week) compared with initial

**TABLE IV Double-Blind Phase: Timolol or Placebo Treatment (Weeks 8 and 10) Compared With Initial Placebo (Week 2)**

| | Group | Week 2 | Week 8 | Week 10 |

| | P | 73.9 ± 13.0 | 75.3 ± 11.8 | 79.8 ± 12.0 |
| Resting SBP (mm Hg) | T | 134.8 ± 21.0 | 127.5 ± 16.7 | 124.5 ± 15.4 |
| | P | 140.7 ± 10.7 | 139.1 ± 16.8 | 138.2 ± 12.1 |
| Exercise duration (s) | T | 261.3 ± 68.8 | 315.1 ± 61.2* | 302.6 ± 63.2 |
| | P | 264.4 ± 112.3 | 291.7 ± 62.6 | 277.3 ± 65.5 |
| Peak exercise HR (beats/min) | T | 121.4 ± 22.1 | 93.6 ± 15.3* | 92.6 ± 13.6† |
| | P | 127.2 ± 25.8 | 130.7 ± 19.6 | 130.3 ± 17.3 |
| Peak exercise SBP (mm Hg) | T | 174.0 ± 28.8 | 148.3 ± 30.7* | 161.8 ± 27.7 |
| | P | 174.5 ± 18.3 | 167.0 ± 18.2 | 175.0 ± 21.7 |
| Peak exercise DP (HR × SBP × $10^{-3}$) | T | 20.2 ± 7.3 | 13.9 ± 4.1* | 15.1 ± 3.9† |
| | P | 22.2 ± 4.8 | 21.9 ± 4.3 | 22.8 ± 4.1 |

* Week 2 versus 8 ($p < 0.05$); † Week 2 versus 10 ($p < 0.05$). AP = episodes of angina pectoris; DP = double product; NTG = sublingual nitroglycerin; P = placebo (n = 10); T = timolol (n = 8).

placebo treatment (10.4 ± 11.4 episodes/week, not significant [NS]). A significant reduction in anginal frequency occurred in these subjects at week 10, from 10.4 ± 11.4 episodes/week with initial placebo to 6.0 ± 8.0 episodes/week with timolol ($p < 0.05$). This lack of efficacy in group data for anginal occurrence at week 8 for timolol subjects was due mainly to 1 individual who had a marked increase in angina compared with his previous placebo treatment. Nitroglycerin consumption was unaltered at weeks 8 and 10 (7.3 ± 10.0 tablets/week and 6.0 ± 9.5 tablets/week, respectively) compared with the initial placebo phase (9.9 ± 13.5 tablets/week, NS).

Individuals randomized to placebo demonstrated no difference in weekly anginal episodes at weeks 8 and 10 (2.2 ± 2.1 episodes/week and 3.9 ± 6.0 episodes/week, respectively) compared with their initial placebo treatment (4.0 ± 3.0 episodes/week, NS). Nitroglycerin usage was also unchanged in these subjects at weeks 8 and 10 compared with initial placebo exposure (1.9 ± 2.2 tablets/week and 3.4 ± 6.1 tablets/week, respectively, versus 3.1 ± 3.6 tablets/week, NS). One of these 10 placebo subjects was omitted from statistical consideration because of unreliable diaries.

*Heart rate and blood pressure:* In patients receiving timolol resting HR was significantly reduced to 58.3 ± 10.5 beats/min at week 8 and 57.6 ± 8.5 beats/min at week 10 compared to the initial placebo treatment period of 8.5 ± 14.5 beats/min (both $p < 0.05$). Resting SBP did not differ in timolol subjects at week 8 or 10 compared with these same patients receiving placebo (127.5 ± 16.7 mm Hg and 124.5 ± 15.4 mm Hg, respectively, versus 134.8 ± 21.0 mm Hg, both NS). Placebo subjects continued at a similar HR of 75.3 ± 11.8 beats/min at week 8 and 79.3 ± 12.0 at week 10 compared with placebo treatment of 73.9 ± 13.0 beats/min (both NS). Resting SPB was also unchanged in placebo patients at weeks 8 and 10 (139.1 ± 16.8 mm Hg and 138.2 ± 12.1 mm Hg, respectively) compared with their initial placebo phase (140.7 ± 10.7 mm Hg, both NS).

*Exercise variables:* Peak exercise HR was substantially lower with timolol (93.6 ± 15.3 beats/min at week 8 and 92.6 ± 13.6 beats/min at week 10) than with placebo (121.4 ± 22.1 beats/min) (both $p < 0.05$). Placebo subjects maintained a similar exercise HR of 130.7 ± 19.6 beats/min and 130.3 ± 17.3 beats/min at weeks 8 and 10, respectively, compared with initial placebo (127.2 ± 25.8 beats/min, both NS). Peak exercise SBP was lower with timolol treatment at week 8 than with placebo (148.3 ± 30.7 mm Hg versus 174.0 ± 28.8 mm Hg, $p < 0.05$), although there was no significant difference at week 10 (161.8 ± 27.7 mm Hg and 174.0 ± 28.8 mm Hg, NS). The double product was significantly lower at weeks 8 and 10 with timolol than with placebo (13.9 ± 4.1 × $10^{-3}$ and 15.1 ± 3.9 × $10^{-3}$, respectively, versus 20.2 ± 7.3 × $10^{-3}$, $p < 0.05$). Exercise duration at week 8 continued to be improved in the timolol group (315.1 ± 61.2 seconds) compared with that in the placebo treatment phase (261.3 ± 68.8 seconds, $p < 0.05$). However, at week 10 this relation did not persist, as timolol patients' exercise duration declined to 302.6 ± 63.2 seconds, compared with 261.3 ± 68.8 seconds in the placebo treatment period (NS).

Subjects randomized to placebo treatment did not differ in exercise duration at weeks 8 or 10 (291.7 ± 62.6 seconds and 277.3 ± 65.5 seconds, respectively) compared with initial placebo treatment (264.4 ± 112.3 seconds, both NS). Peak exercise HR was similar at weeks 8 and 10 (130.7 ± 19.6 beats/min and 130.3 ± 17.3 beats/min; respectively) in these subjects compared with the initial placebo treatment phase (127.2 ± 25.8 beats/min, both NS). No difference in peak exercise SBP was observed at week 8 or 10 (167.0 ± 18.2 mm Hg and 175.0 ± 21.7 mm Hg, respectively) compared with initial placebo in these subjects (174.5 ± 18.3 mm Hg, both NS). The double product was unchanged in these patients at weeks 8 and 10 compared with initial placebo exposure (21.9 ± 4.3 × $10^{-3}$ and 22.8 ± 4.1 × $10^{-3}$, respectively, versus 22.2 ± 4.8 × $10^{-3}$, NS).

*S-T segment depression:* Fourteen subjects had at least 1 mm exercise-induced S-T segment depression until week 8. This group included 6 patients randomized to timolol and 8 randomized to placebo treatment. The appearance of 1 mm S-T segment depression was insignificantly delayed in timolol subjects at week 8 (261.7 ± 55.6 seconds) compared with their initial placebo period (224.0 ± 54.0 seconds, NS). Placebo patients had 1 mm S-T segment depression at week 8 similar to their initial placebo phase (232 ± 72.7 seconds versus 249.0 ± 106.5 seconds, NS).

*Adverse effects:* One subject had a mild macular rash during week 9 while receiving timolol. Timolol was continued until week 10 with diminution of this condition. One patient had headache and dizziness during weeks 5 and 6 and was discontinued from the study. No abnormalities in serum electrolytes, blood chemistry determinations, or complete blood count were observed at any point in this investigation.

## Discussion

Our study demonstrates the effectiveness of timolol administered twice daily in controlling objective evidence of myocardial ischemia and functional capacity in patients with chronic angina. This result was demonstrated during both the open-label and double-blind phases of this investigation. During the open-label treatment period, anginal frequency and nitroglycerin consumption decreased while exercise capacity was significantly increased compared with placebo control. There was also a reduction in peak exercise HR, in peak exercise SBP, and in the double product (an index of myocardial oxygen demand) in our subjects receiving optimal timolol dosage. Eight subjects randomized to timolol during the double-blind treatment period continued with enhanced exercise performance when first tested at week 8, although this was not maintained at week 10 when compared with placebo treatment in these patients. Reduction of peak exercise HR and double product was maintained in these subjects at weeks 8 and 10 compared with placebo treatment. Ten placebo patients continued at their previous level of exercise performance compared with initial placebo without a difference in cardiac hemodynamic function or exercise variables. Thus, these data support a significant action of timolol administered every 12 hours in the prevention of myocardial ischemia.

Our results with timolol showed a lack of significant improvement in exercise capacity at week 10, in anginal frequency at week 8, and in nitrate consumption at weeks 8 and 10. Thus, we noted a disparity at week 10 between exercise hemodynamics indicating effective beta blockade and exercise capacity. The basis for this finding is unclear but may be related to several factors. Spontaneous variability in the subjective symptom of angina may account for this observation. Another potential explanation is conversion of the exercise endpoint from angina to fatigue by the beta blocker.[14,15] This possibility is supported by the fact that 2 patients, or 25% of the timolol group, terminated exercise at week 10 because of fatigue compared with the exercise endpoint of angina at week 8. Also, some timolol subjects were exercised closer to 13 hours rather than 12 hours after the drug, which may explain in part the lack of prolongation in exercise capacity. The small number of patients randomized to the timolol treatment group may, in addition, preclude the ability to consistently detect significant differences in exercise performance. Although blood level data are not available in our subjects, compliance with the treatment program appeared satisfactory in view of the consistently significant reduction in rest and exercise peak HR and double product at weeks 8 and 10 in the treated individuals compared with the placebo group. Patients randomized to placebo demonstrated no differences in these variables at weeks 8 and 10 compared with their initial placebo phase.

Tolerance to timolol could have developed in the patients receiving this medication; this would explain the differences between exercise performance at weeks 8 and 10 in this group. This possibility is unlikely in view of similar hemodynamic changes observed in timolol subjects at week 10 compared with week 8. Also, tolerance was not observed by us in other subjects receiving timolol long-term to control mild essential hypertension[7] and is not consistent with the previous experience of multiple investigators utilizing various beta-adrenergic blockers to treat angina pectoris.[2,4]

**Absence of training effect:** The possibility of a training effect does not explain the salutary result on exercise capacity demonstrated by timolol subjects at week 8. However, a training effect, namely, a decline in resting HR and improvement in exercise performance over time with multiple episodes of treadmill exercise, does merit consideration as an explanation of our results. All of our subjects had at least 1 treadmill exercise test before entry into this study. Such acclimation to the treadmill is known to result in subsequent reproducibility of the exercise test.[16] Also, our placebo patients had no decrease in resting heart rate or significant improvement in exercise capacity from initial placebo treatment through completion of the double-blind treatment period. Thus, the presence of any training effect influencing the exercise performance of our patients is unlikely.

**Other investigations:** Our data are consistent with those of other investigators evaluating other beta-adrenergic blocking agents in angina pectoris as well as with previous observations concerning timolol.[11,12,17,18] Thus, Villa et al[19] studied 16 patients with chronic stable angina pectoris by treadmill exercise at peak drug effect in a double-blind crossover investigation. Twelve of 16 subjects had improved exercise tolerance, with an 11% increase in exercise duration and a 20% improvement in total work on timolol. Aronow et al[20] evaluated 23 patients with chronic angina pectoris in a placebo-controlled, double-blind randomized crossover study utilizing bicycle ergometry. Two hours after drug administration, timolol prolonged exercise duration 51% compared with placebo while it substantially decreased the mean maximal amount of exercise-induced ischemic S-T segment depression. Anginal frequency and nitroglycerin consumption were also significantly reduced. Again, as seen in our subjects, timolol reduced resting

HR, peak exercise HR, peak SBP, and double product. In addition, Aronow et al[21] demonstrated an increase in exercise duration of ≥25% in only 3 of 7 coronary patients with timolol when tested 12 hours after drug administration; all 7 patients in this study achieved this degree of improved exercise capacity 2 hours after drug administration. These data are concordant with our findings and suggest an effective action for twice daily timolol in the control of angina pectoris for a certain proportion of these patients.

**Adverse effects:** Beta-adrenergic blockade can produce a number of adverse effects. Few of these are potentially serious; most are bothersome and may be alleviated by adjustment in dose or drug withdrawal.[22] Timolol maleate twice daily was well tolerated in our patients. No serious adverse effects were observed. One subject experienced a macular rash during timolol treatment which resolved in 1 week with continuation of the drug. It is unclear at present whether this reaction is related to the compound. Headaches and dizziness developed in another subject during timolol treatment, and continued into the down-titration phase of the investigation (week 6) before the double-blind phase. No other patient had adverse effects thought to be drug-related.

**Conclusions:** Timolol maleate is an effective agent which can decrease anginal frequency and improve exercise capacity in patients with coronary heart disease and stable angina pectoris. This action can be demonstrated for up to 12 hours after drug administration in some subjects with chronic angina by an increased exercise capacity as well as a decrease in anginal frequency. Resting HR and SBP, peak exercise HR and SBP, and double product are significantly altered by twice-daily administration of this drug. The occurrence of myocardial ischemia as reflected by exercise-induced S-T segment depression can be delayed in some anginal patients receiving twice-daily timolol. Timolol, therefore, can be potentially useful in at least some patients for the treatment of angina pectoris when administered twice daily. However, other patients may require a more frequent dose interval for optimal control of angina pectoris and maximal improvement in exercise performance.

# Regional Coronary Blood Flow During Relief of Pacing-Induced Angina by Nitroglycerin

## Implications for Mechanism of Action

RICHARD M. FUCHS, MD, JEFFREY A. BRINKER, MD, PABLO A. GUZMAN, MD, DEAN E. KROSS, MD, and FRANK C. P. YIN, MD, PhD

**The mechanism for the therapeutic effect of nitroglycerin in stress-induced angina remains controversial; it has been attributed to both increased blood supply to the ischemic myocardium and decreased myocardial oxygen demand. To investigate the contribution of each of these mechanisms, systemic pressures and great cardiac vein flow were measured in 14 patients with single-vessel disease involving the left anterior descending (LAD) coronary artery during the development of pacing-induced angina and after the administration of nitroglycerin while continuing pacing at the angina-provoking rate. Great cardiac vein flow, measured by thermodilution, represents the venous efflux from the LAD territory and therefore provided an index of flow to the poststenotic myocardium. In 11 patients, nitroglycerin was administered systemically (400 to 800 μg sublingually or 200 μg intravenously); angina was relieved in 10, concomitant with a decrease in both great cardiac vein flow (from 123 ± 29 to 98 ± 29 ml/min, $p < 0.001$) and mean aortic pressure (from 118 ± 22 to 104 ± 22 mm Hg, $p < 0.001$). In contrast, when 75 μg of nitroglycerin was administered directly into the left main coronary artery of 7 patients, it produced a small increase in great cardiac vein flow (from 108 ± 32 to 125 ± 31 ml/min, $p = 0.059$), no change in aortic pressure, and no relief of angina. This study suggests that nitroglycerin's major beneficial action in pacing-induced angina is unrelated to direct effects on the coronary circulation and is likely related to its cardiac unloading effect.**

Since Brunton[1] first attributed the antianginal effect of nitrates to decreased "arterial tension" in 1867, the mechanism of their therapeutic action has been the subject of controversy.[2] The debate has centered on the relative importance of reduced myocardial oxygen demand due to cardiac unloading[3–12] and improved myocardial blood supply due to dilation of epicardial coronary arteries (including stenotic regions),[13–18] increased collateral blood flow,[19–24] and redistribution of coronary flow toward ischemic regions.[25–27] Most studies addressing the mechanism of nitrates' action have examined systemic hemodynamic function and coronary blood flow after administration of nitroglycerin to animals with acute coronary ligations or to patients with coronary artery disease at rest; they have not generally examined the effect of nitroglycerin in patients during episodes of symptomatic ischemia. Acute coronary ligation in the dog may not be an appropriate model for stress-induced ischemia in man, and the effect of nitroglycerin on patients in the resting, asymptomatic state may not necessarily reflect the mechanism of its antianginal action. In the one classic study in which coronary blood flow *was* measured in patients after administration of nitroglycerin during episodes of angina, Ganz and Marcus[7] showed that pacing-induced angina could be relieved by intravenous but not by intracoronary nitroglycerin; unfortunately, during these interventions they measured total coronary sinus blood flow, rather than flow to the specific coronary bed that was ischemic.

To examine the mechanism of nitroglycerin's therapeutic effect in patients with stress-induced angina pectoris, it is necessary to administer nitroglycerin during an episode of angina and to determine how it affects symptoms, systemic hemodynamics, and that portion of coronary blood flow directed to the ischemic myocardium. Therefore, we produced angina by incre-

mental atrial pacing in patients with single-vessel disease involving the proximal LAD coronary artery and administered nitroglycerin by 1 or more of 3 routes (sublingual, intravenous, and intracoronary) while continuing to pace at the angina-provoking rate. Great cardiac vein flow, representing blood flow to the poststenotic myocardium, was determined in the basal state, during pacing-induced angina, and after administration of nitroglycerin. Systemic pressure responses and great cardiac vein flow measurements were related to the symptomatic response to nitroglycerin.

## Methods

**Patient selection:** The subjects were selected from patients undergoing diagnostic cardiac catheterization and coronary angiography at the Johns Hopkins Hospital. All subjects had >50% arteriographic narrowing of the LAD coronary artery proximal to the origin of its first major diagonal branch, without significant narrowing in the right or circumflex coronary artery. Patients were excluded if they had significant valvular or congenital heart disease, previous cardiac surgery, previous myocardial infarction, congestive heart failure, cardiomegaly visible on chest roentgenography, or an abnormal resting electrocardiogram. Informed consent was obtained in each case.

**Procedure:** All patients were studied in the fasting state after premedication with diazepam, diphenhydramine, and atropine. All precatheterization medications were continued. Routine diagnostic cardiac catheterization, coronary angiography, and left ventriculography were performed using the Judkins technique. A triple thermistor thermodilution pacing catheter (Wilton Webster Laboratories, Altadena, California) was then placed through a right brachial vein incision and inserted into the coronary sinus with the distal sampling thermistor advanced to the great cardiac vein. The patient's heart rate was progressively increased by atrial pacing in increments of 10 to 20 beats/min, according to a protocol previously described.[28] Great cardiac vein flow, representing the venous efflux from the myocardium supplied by the LAD coronary artery, was determined[28–30] at rest, during pacing-induced angina, and after the administration of nitroglycerin. Phasic and mean aortic pressure and 12-lead electrocardiogram were monitored throughout. In 7 patients, 400 to 800 μg of nitroglycerin was administered sublingually during pacing-induced angina, and great cardiac vein flow was determined 1 to 3 minutes later; in 4 of these patients left ventricular pressure was monitored continuously as well. In an additional 7 patients, nitroglycerin was administered as a 75 μg bolus injection into the left main coronary artery during pacing-induced angina, and great cardiac vein flow was determined continuously for the next 30 to 60 seconds; the greatest alteration in flow was recorded. In 4 of these patients, a 200 μg dose of nitroglycerin was then rapidly injected intravenously while pacing at the same rate with persistence of angina pectoris, and great cardiac vein flow was determined 15 to 60 seconds later. Four of the patients who received intracoronary injections of nitroglycerin during pacing-induced

Format and abbreviations as in Table I.

angina had flow measurements repeated after turning off the pacemaker (with return to baseline heart rate and complete resolution of angina) and again after a 75 μg intracoronary bolus injection of nitroglycerin at this baseline heart rate.

**Statistical analysis:** A paired-samples *t* test was used to assess changes in aortic pressure, left ventricular end-diastolic pressure (LVEDP), and great cardiac vein flow with each method of administration of nitroglycerin. All data are presented as mean ± standard deviation. Differences were considered significant when the p value was <0.05.

## Results

**Patient characteristics:** Eleven of the 14 patients were male; mean age was 54 years (range 36 to 64). All had significant narrowing of the proximal left anterior descending coronary artery (Tables I and II) without significant narrowing in other coronary arteries. Three patients had angiographically visible right to left collateral vessels.

**Effect of incremental atrial pacing:** During incremental atrial pacing, all 14 patients developed typical angina pectoris with electrocardiographic S-T segment depression; peak heart rate averaged 140 beats/min. Mean aortic pressure rose from 98 ± 11 mm Hg to 112 ± 24 mm Hg ($p = 0.01$), and great cardiac vein flow rose from 68 ± 23 to 116 ± 30 ml/min ($p < 0.001$) (Tables I and II). Eleven of the 13 patients in whom sequential flow measurements were performed demonstrated the flow limitation phenomenon we have previously described[28]: each increment in heart rate led to an increase in great cardiac vein flow until a certain point was reached; further increase in heart rate beyond that point led to no further augmentation of flow but did lead to angina and electrocardiographic signs of ischemia. In the 4 patients in whom LVEDP was measured, there was no significant change with pacing (15 ± 3.6 mm Hg at rest and 14 ± 13 mm Hg at peak heart rate).

**Effect of systemic nitroglycerin (Table I, Fig. 1):** In 10 of the 11 cases in which nitroglycerin was administered systemically (sublingually or intravenously) during pacing-induced angina, the angina was wholly or partially relieved despite continuation of atrial pacing at the same rate at which angina was produced. S-T segment depression decreased in 8 of these cases. The antianginal effect of sublingual nitroglycerin was usually

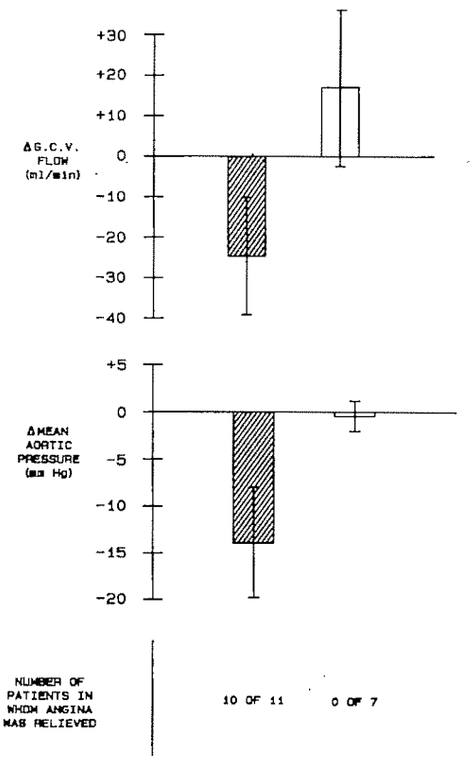

**FIGURE 1.** The effects of nitroglycerin administered during pacing-induced angina on great cardiac vein (G.C.V.) flow, mean aortic pressure, and clinical symptoms. The **hatched bars** indicate the response to systemic (sublingual or intravenous) nitroglycerin; the **open bars** indicate the response to intracoronary nitroglycerin. **Brackets** indicate standard deviations.

manifest in 1 to 3 minutes, that of intravenous nitroglycerin in 30 to 90 seconds. In every case, relief of symptoms was preceded by a fall in aortic pressure and a fall in great cardiac vein flow. In response to sublingual nitroglycerin, mean aortic pressure fell from 129 ± 17 to 114 ± 19 mm Hg ($p = 0.002$) and great cardiac vein flow fell from 124 ± 29 to 102 ± 28 ml/min ($p = 0.004$); in each of the 4 cases in which it was measured, LVEDP fell—from a mean of 14 ± 13 to 6.0 ± 5.0 mm Hg (not significant). The responses of great cardiac vein flow, aortic pressure, and LVEDP in a representative patient are illustrated in Figure 2.

In response to intravenous nitroglycerin, mean aortic pressure fell from 100 ± 19 to 88 ± 18 mm Hg ($p = 0.003$) and great cardiac vein flow fell from 121 ± 34 to 91 ± 33 ml/min ($p = 0.049$).

**Effect of intracoronary nitroglycerin (Table II, Fig. 1):** In contrast to the relief of ischemia with systemic nitroglycerin, when the drug was administered by the intracoronary route during pacing-induced angina, no patient had relief of symptoms and no patient showed improvement of ischemic changes on electrocardiography, despite a modest increase in great cardiac vein flow in most cases (108 ± 32 to 125 ± 31 ml/min, $p = 0.059$). In all cases, great cardiac vein flow returned to prenitroglycerin levels by 60 seconds after injection. There was no discernible effect of the intracoronary nitroglycerin on aortic pressure. To assess the responsiveness of these patients' coronary arteries to this dose of nitroglycerin, the same dose was administered to 4 patients (Patients 9, 11, 12, and 13) at the end of the study, after pacing had been discontinued. In these 4 patients, whose great cardiac vein flow had risen by 26 ± 22 ml/min in response to intracoronary nitroglycerin administered during peak pacing, great cardiac vein flow increased by 57 ± 29 ml/min in response to the same dose administered at the basal, nonanginal heart rate ($p = 0.009$).

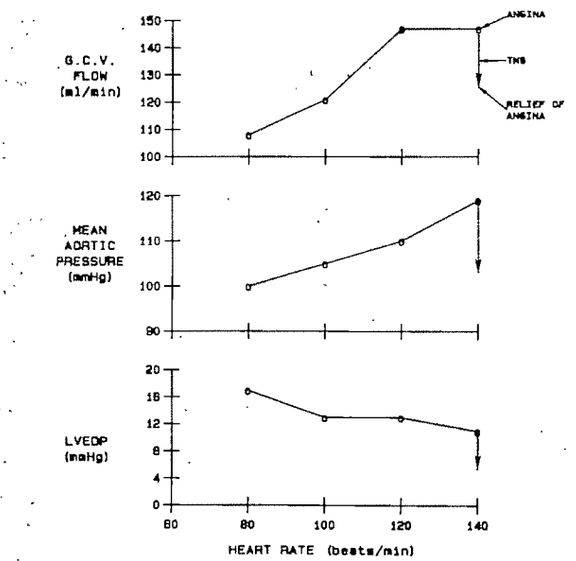

**FIGURE 2.** The effects of incremental atrial pacing and sublingual nitroglycerin (TNG) on great cardiac vein (G.C.V.) flow, mean aortic pressure, and LVEDP in a representative patient with single-vessel LAD disease. The **solid line and open circles** indicate the effects of incremental atrial pacing; note the development of flow limitation as the heart rate was increased from 120 to 140 beats/min. Angina and S-T segment changes occurred at a heart rate of 140 beats/min. The **dotted line and arrow** indicate the effects of 400 μg of nitroglycerin administered sublingually while continuing pacing at 140 beats/min: great cardiac vein flow, aortic pressure, and LVEDP decreased, and angina was relieved.

## Discussion

The present study demonstrates that (1) sublingual and intravenous nitroglycerin are capable of relieving pacing-induced angina pectoris concomitant with reductions in systemic pressure and despite reductions in blood flow to the poststenotic coronary bed, and (2) intracoronary nitroglycerin does not relieve pacing-induced angina despite a modest increase in blood flow to the poststenotic coronary bed. The use of patients with single-vessel disease is crucial, because only for such patients can one be reasonably certain in which coronary bed ischemia is occurring. The use of thermodilution flow measurements in the great cardiac vein provides a measure of the flow, both direct and collateral, to the LAD territory.[28,30–33]

The thermodilution technique enables one to measure transmural flow to the LAD territory but does not allow differentiation of regional blood flow within the LAD bed. Thus, it is possible that nitroglycerin-induced relief of angina might be associated with a relative preservation of blood flow to the subendocardium. Such an effect has been observed in dogs[12] and has been attributed to nitroglycerin's cardiac unloading effect with consequent reductions in diastolic left ventricular pressure and in intramyocardial pressure surrounding small subendocardial coronary vessels. An *absolute* increase in flow to the subendocardium seems quite unlikely, given the simultaneous decrease in perfusion pressure, myocardial demand, and transmural flow.

Although systemic hemodynamics during exercise are not identical to those during incremental atrial pacing, increased myocardial oxygen demand due to increased heart rate-blood pressure product has been implicated in the pathogenesis of angina in both situations.[34,35] Furthermore, administration of nitroglycerin in both situations leads to a reduction in systemic blood pressure.[36] Thus, it is likely, although unproven, that the results we obtained after administration of nitroglycerin during pacing-induced angina apply to most cases of exertional angina as well.

The decrease in blood flow to the poststenotic myocardium we observed after systemic administration of nitroglycerin is probably due to the combination of decreased coronary perfusion pressure and reduced myocardial oxygen demand. In spite of this decrease in flow to the poststenotic vascular territory, objective and subjective signs of ischemia were almost invariably improved. Although there are suggestions that nitroglycerin may have a direct depressant effect on myocardial metabolism[37–39] and may increase oxygen availability to the myocardium by altering the oxyhemoglobin dissociation curve,[39] reduced oxygen de-

mand due to cardiac unloading seems the most likely mechanism for its therapeutic effect.[6–8,10,11] The decrease in aortic and left ventricular pressures we observed after systemic administration of nitroglycerin are certainly compatible with decreased ventricular wall tension associated with cardiac unloading. However, other possible noncoronary effects of nitroglycerin (such as depression of oxygen demand unassociated with cardiac unloading) have not been excluded.

We have previously shown that incremental atrial pacing in patients with isolated LAD disease leads to progressive increases in great cardiac vein flow until a point of flow limitation is reached; angina and S-T segment changes occur at that point.[28] After the development of flow limitation and ischemia during incremental pacing in the present study, intracoronary nitroglycerin produced a small increase in flow to the LAD territory in most patients. This increase in flow after intracoronary nitroglycerin may be due to dilation of the coronary stenosis,[13–18] increase in collateral flow to the LAD bed, or further vasodilation in nonischemic (for example, subepicardial) regions within the LAD bed. Indeed, animal experiments have suggested that, in the presence of a critical coronary artery stenosis, some vasodilational reserve is present but that it is limited to the subepicardium.[40] Thus, it is not surprising that a moderate ability to augment transmural flow exists in patients during angina but that such augmentation is not associated with relief of the angina; presumably, it is directed principally to nonischemic regions. The failure of intracoronary nitroglycerin to relieve angina despite increased coronary flow, in other studies[7,41] as well as in ours, strongly suggests that increased perfusion of poststenotic beds does not play a major role in nitroglycerin's therapeutic action in pacing-induced angina.

The present study does not negate the fact that nitroglycerin improves both symptoms and myocardial perfusion in some cases by relieving coronary artery spasm; nor does it imply that nitroglycerin is not capable of increasing subendocardial perfusion or collateral flow under certain circumstances. However, it does suggest that nitroglycerin's major beneficial action in most cases of stress-induced angina pectoris is unrelated to direct effects on the coronary circulation and is likely related to its cardiac unloading effect.

# Implications of Increased Myocardial Isoenzyme Level in the Presence of Normal Serum Creatine Kinase Activity

GARY V. HELLER, MD, PhD, ALVIN S. BLAUSTEIN, MD, and JEANNE Y. WEI, MD,
*With the technical assistance of* DANIEL GEER

**Although increased serum creatine kinase (CK) activity in the presence of an increased level of myocardial-specific isoenzymes (CKMB) has been strongly associated with acute myocardial infarction, the significance of an increased serum CKMB level in the presence of a normal total CK level is uncertain. In 335 consecutive patients suspected of having an acute myocardial infarction and 71 control subjects, peak serum CKMB and CK levels were correlated with the presence of other clinical criteria for acute myocardial infarction: (1) typical chest pain, (2) increased myocardial lactate dehydrogenase ($LDH_1/LDH_2$), (3) acute electrocardiographic changes (new or ST-T wave changes with evolution), and (4) an elevated CKMB level on 2 or more determinations or a typical CK curve. No control subject had an increase in CK or CKMB or any of the 4 criteria for myocardial infarction. Of the 176 subjects with normal CK and normal CKMB (Group 1), only 11% had more than a single criterion, and none had more than 2 criteria consistent with myocardial injury. In contrast, of the 83 with elevated CK and CKMB levels (Group 2), 93% had 2 or more and 81% had 3 or more of the 4 criteria. Of the 63 patients with elevated CKMB but a persistently normal CK (Group 3), 65% had 2 or more criteria for acute myocardial infarction and 77% had subendocardial electrocardiographic changes; these patients resembled those with both elevated CK and MB. The phenomenon of elevated CKMB with normal CK occurred in 20% of the patients aged ≥70 years but in only 10% of the younger group ($p < 0.01$). These findings suggest that elevated CKMB with normal CK likely represents definite myocardial injury, is more common in the elderly, and should be considered part of the spectrum of nontransmural myocardial infarction.**

The irreversible disruption of myocardial cell membranes results in the release into the serum of specific intracellular constituents, among which are CK and its isoenzymes. The application of techniques for the measurement of these myocardial enzymes of CK has enhanced the physician's ability to distinguish patients with frank myocardial injury from those with reversible ischemia or noncardiac symptoms.[1-3] The definition of unequivocal infarction has been based on an increase in the CK activity above the normal range, the simultaneous appearance of CKMB, and a characteristic disappearance curve.[4] Because it is now possible to sensitively measure CKMB, a group of patients has been identified in whom CKMB is elevated but total CK remains within normal limits.[5] The significance of this finding has not been clearly established, and it remains uncertain whether or not this represents a subtle form of myocardial injury.[1,6-8] It was hypothesized that, were this finding to represent cell death, other evidence indicative of myocardial injury should be present. Conversely, the constellation of normal CK and elevated CKMB should not occur in asymptomatic patients. The present study was undertaken to clarify the nature of the relation between these enzymatic findings and myocardial infarction.

## Methods

**Patients:** The charts of 1,021 consecutive patients admitted to the Beth Israel Hospital between March and November 1980 in whom CK and CKMB determinations had been requested were reviewed. Patients in whom a potential noncardiac source of CK had been documented were excluded: those with seizure, trauma, intercurrent surgery, or musculoskeletal disorders. Patients with the electrocardiographic finding of left bundle branch block and without previous tracings were also excluded. All patients with the diagnosis of myocardial infarction in whom multiple enzyme determinations were available were included; 10 patients with only 1 CK measurement were not included.

Three hundred thirty-five patients comprised the study group. In all, a minimum of 3 enzyme determinations within 36 hours of admission were available; the first of these was obtained at the time of symptomatic presentation and the second was generally obtained within 12 to 18 hours of the first. Seventy-one asymptomatic patients hospitalized for elective surgery, of a similar age distribution, and with a remote history of coronary artery disease served as control subjects; these patients had at least 1 determination of cardiac enzymes while in the hospital. In each patient, the following clinical and laboratory data were obtained: age, sex, presenting symptoms, the admitting physicians' initial clinical impression, serial 12-lead electrocardiograms, admission chest

CK− = creatine kinase within normal laboratory range 200 IU; CK+ = creatine kinase >200 IU; MB− = creatine kinase myocardial enzyme <6% of total (considered normal range); MB+ = creatine kinase myocardial enzyme >6%.

roentgenogram, serum glutamic oxaloacetic transaminase (SGOT), lactate dehydrogenase (LDH), and isoenzymes, as well as CK and its isoenzymes. In the text and analysis, the term *typical chest pain* is used to summarize the following general descriptions on the patient's record: ischemic pain, angina, crushing substernal pain, and substernal pressure or aching in the chest, back, or jaws with radiation into the left or both arms. All electrocardiograms were reviewed by at least one of us; the few discrepancies with official readings were settled by consensus. Evidence of transmural infarction was considered present if a new Q-wave or characteristic evolution, or both, was observed on serial tracings. Subendocardial infarction or ischemia was diagnosed if new S-T segment depression or T-wave inversion, or both, persisted for >24 hours. Nonspecific S-T segment and T-wave changes were considered significant if they represented an interval change in the electrocardiogram, were localized in distribution, and persisted for >24 hours. The interpretation of the chest roentgenogram was the official reading made by the radiology department.

Laboratory data were processed routinely in the clinical laboratory at the Beth Israel Hospital. Myocardial isoenzymes were measured with agar gel electrophoresis (Corning). Before densitometric quantification, a visual inspection of the agar plate was performed, and only those with a visible CKMB band underwent further analysis. CKMB results are reported as percentages and not in international units, because accurate measurement of international units of MB using this technique would require eluting the MB band after it is removed from the agarose plate,[9] a procedure not performed in the laboratory. A CKMB level of ≤5% is considered within normal limits. In the clinical laboratory LDH isoenzymes are quantitated routinely when the total LDH level exceeds 220 IU. In all 147 of 249 patients in Group 1 and the control group, all patients in Group 2, 55 of 63 patients in Group 3 and 18 of 21 patients in Group 4 had at least 1 LDH isoenzyme measurement. For the purposes of this study, when LDH isoenzymes were not measured it was assumed that the myocardial isoenzyme/liver isoenzyme ($LDH_1/LDH_2$) did *not* reveal evidence of myocardial necrosis. This assumption may well have resulted in the incorrect classification of some patients with myocardial injury as normal. If an estimated 15% of patients with no LDH isoenzyme determinations were assumed to have $LDH_1 \geq LDH_2$, this would have resulted in approximately 3 patients in Group 1 and 2 patients in Group 3 being reclassified on the basis of our criteria for myocardial injury (see Table III).

Results throughout are expressed as the mean ± standard error of the mean. Where statistical methods are applied, the specific test is indicated.

## Results

The study was designed to evaluate the significance of a particular enzymatic profile. The initial identification of subjects was based only on the requirement that CKMB determination had been requested by the physician and performed by our laboratory. We were therefore initially unaware of the clinical indication for the test. Patient groups were identified on the basis of the CK and CKMB levels falling within or exceeding normal limits for the laboratory. This resulted in 4 identifiable groups: Group 1 had normal CK and CKMB (CK−MB−; n = 173); Group 2 had elevated CK and CKMB (CK+MB+; n = 83); Group 3 had a normal CK and elevated CKMB (CK−MB+; n = 63); and Group 4 had elevated CK and normal CKMB (CK+MB−; n = 16).

Five patients in the control group and all Group 4 patients had CK elevation with normal MB that defied explanation on the basis of available data. These patients will not be characterized further.

Table I lists the clinical characteristics of the 4 groups and control subjects. Group 1 consisted of patients in whom infarction was clinically excluded by history, physical examination, electrocardiography, and enzymatic analysis. In contradistinction, Group 2 included patients in whom the clinician believed unequivocally that myocardial infarction had occurred. Group 3 included patients in whom the diagnosis of infarction was uncertain. This last group was significantly older than the other ($p < 0.01$, one-way analysis of variance). The incidence of typical chest pain and electrocardiographic changes consistent with transmural or nontransmural infarction was highest in Group 2 (86% and 87%, respectively). The percentage of patients with chest pain was almost identical in Group 1 and Group 3 patients, but electrocardiographic changes were much more common in Group 3 (65% versus 17%). Not surprisingly, patients in Group 2 more frequently had electrocardiographic findings compatible with a transmural event, whereas those in Group 3 had predominantly nontransmural changes. Chest pain and electrocardiographic changes were absent in the control group (Group A, Table I).

Enzymatic data are listed in Table II. In Group 2, CKMB% averaged 18 ± 5% and all other enzymatic in-

* Entry indicates number of patients and percentage of the total in each group with the finding.
CK = serum creatine kinase, normal ≤200 IU/liter; LDH = serum lactate dehydrogenase activity, normal ≤220 IU/liter; $LDH_1/LDH_2$ = ratio of cardiac to liver isoenzymes of lactic dehydrogenase; MB = myocardial specific isoenzyme of DK; (+) if ≥6% of total CK; SGOT = serum glutamic oxalacetic transaminase activity, normal ≤40 IU/liter.

dexes were higher than in all other groups and the control group. In Group 3, although the peak CK total was well within normal limits, it was significantly higher than in Group I and the control group ($p < 0.05$, analysis of variance); CKMB% was 12 ± 6% in this group, a value well above the upper limits of normal (5%) in our laboratory. In Group 3, the peak CK level (98.0 ± 11.3 IU) was more than double the basal CK level (47.0 ± 9.5 IU; $p < 0.01$, paired $t$ test) measured either on admission or at discharge. These data suggest that any CKMB level >5 IU is abnormal (98.0 × 5%). Although neither total peak SGOT nor LDH effectively discriminated among control, Group 1, and Group 3 patients, 20% (12 of 63) of Group 3 patients did demonstrate reversal of LDH isoenzymes. Thus, examination of clinical and enzymatic data suggested that Group 3 represented a population with characteristics more closely resembling Group 2 than Group 1 or control patients.

To further characterize the study group and determine the occurrence of clinically significant events in this group, a set of criteria were identified other than a single elevated CK or CKMB level which most clearly differentiated patients in whom myocardial infarction had been clinically excluded (Group 1) from those in whom infarction was evident (Group 2). These criteria were typical chest pain, new electrocardiographic changes, and $LDH_1/LDH_2 \geq 1$. In order to minimize the likelihood of increased CKMB+ occurring as a random event, we also considered the presence of increased CKMB+ on more than 1 occasion or the presence of a characteristic CK curve to be a criterion. A patient could thus have a maximum of 4 positive criteria. These results are presented in Table III. Eighty-nine percent of patients in Group 1 had a maximum of a single criterion; none had more than 2 criteria. In contrast, 93% of patients in Group 2 had 2 or more criteria. Therefore, in the evaluation of Group 3, a minimum of 2 criteria were required to qualify as strong evidence for myocardial injury. Sixty-five percent of the patients in this group had 2 or more criteria. In sharp contrast, no patient in the control group had a single positive criterion.

**TABLE III Diagnostic Criteria***

| Criteria Number | Study Patients | | | Control Patients |
|---|---|---|---|---|
| | Group 1: CK−MB−† | Group 2: CK+MB+ | Group 3: CK−MB+ | Group A: CK−MB− |
| 0 | 43 | 1 | 6 | 100 |
| 1 | 46 | 6 | 29 | 0 |
| 2 | 11 | 12 | 33 | 0 |
| 3 | 0 | 27 | 24 | 0 |
| 4 | 0 | 54 | 3 | 0 |

* Diagnostic criteria = typical chest pain, new ECG changes, $LDH_1/LDH_2 \geq 1$, CKMB+ more than once or typical CK curve; maximum of 4 criteria per patient. † Percentage of total in each group with designated number of criteria.

We sought to clarify the relation between the clinical criteria for acute myocardial infarction and the peak percentage of CKMB in Group 3 patients. All the patients in Group 3 were subclassified into 4 groups based on the number of positive clinical criteria for infarction. For the patients with no criteria (n = 4), mean CKMB was 7.5 ± 0.3%, whereas those with 1 criterion (n = 16) mean CKMB was 9.6 ± 1.1%. The means for those with 2 (n = 29) and 3 (n = 13) criteria were 10.2 ± 1.5% and 13.5 ± 1.5%, respectively. In 1 patient with 4 positive criteria, peak CKMB was 29%. Although there is some overlap in the range of CKMB for the different numbers of diagnostic criteria, the mean percentage of CKMB increases as the number of positive criteria for acute infarction increases ($p < 0.05$, one-way analysis of variance).

## Discussion

In our study, patients with an enzymatic profile characterized by the presence of an elevation in CKMB on at least 1 determination without an increase in total CK above normal had a high incidence of new nontransmural electrocardiographic changes and a 20% incidence of LDH isoenzyme reversal. Laboratory evaluation often demonstrated an increase in CK to twice basal levels during the hospital course. In contrast, new electrocardiographic changes, CK fluctuations, and reversed LDH ratio were distinctly unusual in Group 1 patients and absent among control subjects. We interpret these data to indicate that patients with positive CKMB but without elevation of total CK had clinical features similar to those with transmural infarction and should be considered to have had nontransmural myocardial injury.

Reports bearing directly on such patients are scarce. D'Souza et al[10] examined a clinically similar group of patients, describing details of CK and LDH isoenzymes. In all, 24 patients were identified in whom the highest

recorded total CK was within normal limits but in whom CKMB was detected. Eleven of these patients had a reversed LDH ratio, 5 of whom had electrocardiographic evidence of nontransmural injury. In another recent study,[5] 20% of 724 consecutive patients admitted to coronary care unit for chest pain had a normal CK but elevated CKMB level utilizing a laboratory method similar to that used in our study. Of these 69 patients, 17% had electrocardiographic evidence of new transmural infarction and 28% had an LDH isoenzyme reversal, figures similar to those in our corresponding patients (20% and 20%, respectively). However, our study differs in that it was designed to determine whether patients with normal CK and elevated CKMB had a clinical and biochemical profile consistent with myocardial injury. Thus, we required only that patients have CK isoenzymes measured without prior knowledge of their clinical presentation or other objective data. On the basis of a composite measure that discriminated patients with transmural infarction from those in whom myocardial infarction was clinically excluded, Group 3 closely resembled those with myocardial infarction. It seems reasonable, therefore, to consider them as having had some myocardial necrosis.

Another aim of the study was to make a preliminary characterization of this group of patients. Group 3 patients were, on the average, older than those in other groups (Table I). Their relative senescence may have a bearing on the low incidence (51%) of presentation with typical chest pain; many patients presented with shortness of breath, syncope, weakness, or abdominal symptoms. This tendency for older patients to present in an atypical fashion has been reported in several studies.[11,12] The increased incidence of this more subtle form of injury in the elderly (20% in patients over age 70, 9% in patients under age 70) may be due to several factors: the distribution of atheromatous lesions, the presence of more abundant collateral vessels, a lower rate of of myocardial oxygen consumption or a lower basal CK activity in the elderly, and perhaps a delay in obtaining therapy because of the atypical nature of the symptoms.

In light of the paucity of information on this enzymatic profile, it seems appropriate to speculate on its place in the clinical spectrum of active coronary disease. In previous clinical descriptions, prolonged or frequent episodes of pain unresponsive to nitroglycerin and associated with localized ST-T wave changes identified patients with nontransmural necrosis.[13] In other studies, these descriptions indicated impending infarction or even a poor prognosis,[14–16] and it is likely that recent reports of positive infarct scintigrams in patients with unstable angina[17,18] include this group of patients. In a recent clinical study, Neill et al[19] performed coronary angiography in patients with coronary insufficiency at the time of hospitalization for the acute episode and 4 months later. Reversible ST-T wave changes frequently corresponded to the anatomic distribution of a severely stenosed vessel. Of 30 electrocardiographic/angiographic correlations, 9 vessels progressed to complete occlusion during the follow-up period. Taken in concert with these studies, our data seem to identify Group 3 patients as a subset of those with an acute coronary syndrome in whom nontransmural necrosis has occurred and who may be at future risk for morbid and mortal events.

In summary, in this study the patients with a CK−MB+ profile have clinical and laboratory characteristics similar to those with typical infarction and distinct from those in whom infarction is excluded. This profile often occurs in an elderly population with a relatively high incidence of atypical ischemic symptoms but with electrocardiographic changes and other laboratory data consistent with necrosis. Our data also suggest that each patient's basal level of CK serve as his reference, because an elevation to at least twice basal levels was observed in the majority of Group 3 patients, even though the maximal CK level remained normal. One may state with a fair degree of confidence that the presence of an elevated CKMB level with a normal CK level, especially in elderly patients, is frequently accompanied by several other criteria associated with myocardial infarction and should be interpreted as definite myocardial damage.

**Acknowledgment:** We thank Deborah Marbut Blaustein and Kathleen Tynan for their help in preparing the manuscript, and Gary Horowitz, MD, who aided us in accessing the laboratory data used in the study.

# Spectrum of Global Left Ventricular Responses to Supine Exercise

## Limitation in the Use of Ejection Fraction in Identifying Patients With Coronary Artery Disease

MARY D. OSBAKKEN, MD, PhD, CHARLES A. BOUCHER, MD, ROBERT D. OKADA, MD, JOHN B. BINGHAM, MD, H. WILLIAM STRAUSS, MD, and GERALD M. POHOST, MD

**Left ventricular function was evaluated with rest and supine bicycle exercise-multigated blood pool scans in 53 patients who had previously undergone coronary angiography for evaluation of a chest pain syndrome. There were 21 normal patients (<25% stenosis in any coronary artery, left ventricular end-diastolic pressure ≤12 mm Hg, and normal left ventriculography) and 32 patients with coronary artery disease (CAD) (>50% narrowing in 1 or more major coronary arteries). Thirty-two (60%) were receiving propranolol at the time of the study. The normal patient group had a significant increase in mean ejection fraction (EF) during exercise (+0.08 ± 0.09), while the CAD group had no increase (0 ± 0.11; p <0.05). Mean end-systolic volume decreased significantly in the normal group (−5 ± 8 ml/m$^2$) but demonstrated no significant change in the CAD group (1 ± 12 ml/m$^2$; p <0.05 compared with normal patients). There was no significant change in mean end-diastolic volume in either group. Mean ejection rate, mean peak systolic pressure/end-systolic volume ratio, and mean pulmonary blood volume ratio also differed in the normal versus CAD patients. Despite mean differences, there was considerable overlap in both groups of individual EF responses: 8 of 21 (38%) of the normal group did not have an increase in EF of 0.05 with exercise, while 15 of 32 (47%) of the CAD group did have an increase in EF of 0.05 with exercise. However, the addition of peak systolic pressure/end-systolic volume ratio and pulmonary blood volume (exercise/rest) ratio improved the sensitivity for detecting CAD from 53 to 84% without adversely affecting specificity. Thus, there is a wide spectrum of left ventricular EF responses to supine exercise. In our patient population, EF alone was an insensitive and nonspecific marker of CAD. The addition of other parameters of global left ventricular function, which may be generated using radionuclide angiography, helps distinguish patients with CAD from normal subjects.**

Radionuclide blood pool imaging offers a noninvasive means of assessing left ventricular function at rest and during maximal exercise. The adequacy of left ventricular function during exercise has been proposed as a reliable method for identifying patients with CAD.[1-13] Although this measurement assesses the adequacy of the coronary circulation only indirectly, it appears to have diagnostic value because many patients with significant coronary stenosis have an impaired left ventricular contractile response to exercise compared with normals. The ejection fraction is the most widely used objective measure of left ventricular contractile function because it is easily and accurately measured.[14,15] Normal patients reportedly have an increase in EF during exercise of ≥0.05.[5] However, because it is a ratio of 2 physiologic parameters, stroke volume and end-diastolic

volume; because it may be affected by changes in heart rate, preload, or afterload; and because exercise is a complex intervention, changes in EF alone may not completely define the adequacy of left ventricular performance during exercise stress.[16,17] Although EF is often the only parameter quantitated during exercise-multigated blood pool scanning, its relation to the presence of coronary disease has not been clarified. Furthermore, other parameters of global left ventricular function may be derived, such as ejection rate,[2] end-diastolic volume,[3,4,9] the ratio of peak systolic pressure to end-systolic volume,[11] and pulmonary blood volume ratio,[6] and their usefulness in relation to EF in the evaluation of CAD has not been clearly defined. In this study, the changes in left ventricular EF during supine bicycle exercise were compared with changes in end-diastolic volume, end-systolic volume, and pulmonary blood volume ratio in patients with or without CAD. The data help to clarify the changes in global left ventricular function to be anticipated in patients with coronary disease.

## Methods

**Patient population:** Fifty-three patients undergoing cardiac catheterization for a stable chest pain syndrome had rest and exercise-multigated blood pool scanning.[12] Patients with unstable or refractory angina pectoris, congestive heart failure, or left ventricular aneurysm were excluded. Twenty-one patients with <25% stenosis measured in at least 2 angiographic projections in all coronary vessels and with left ventricular end-diastolic pressure ≤12 mm Hg at rest were defined as normal; this group was comprised of 10 males and 11 females with a mean age of 47 ± 12 years (mean ± 1 standard deviation). None had mitral valve prolapse. Thirty-two patients with >50% diameter luminal narrowing measured in at least 2 angiographic projections in 1 or more major coronary vessel were defined as having CAD and included 26 males and 6 females with a mean age of 53 ± 9 years. Four patients had single-vessel disease, 16 double-vessel disease, and 12 triple-vessel disease. Eleven patients had a documented previous myocardial infarction. Thirty-two patients were receiving propranolol and included 8 of 21 (38%) normal and 24 of 32 (75%) CAD patients. Propranolol was not routinely discontinued before exercise because of reluctance of the patients' physicians in our institution. Nitrates were withheld for 4 hours before the performance of the stress test. No patient was receiving digoxin.

**Scan acquisition:** Each patient was given an intravenous injection of stannous pyrophosphate (Pyrolite, New England Nuclear, North Billerica, Massachusetts) followed within 30 minutes with 20 mCi of technetium-99m pertechnetate for in vivo labeling of the red blood cells.[18] After 10 minutes of tracer equilibration, supine multigated blood pool images were acquired in the anterior and the left anterior oblique view for optimal visualization of the interventricular septum. An Ohio Nuclear Series 420 Anger Camera with a medium sensitivity all-purpose parallel hole collimator (Technicare, Cleveland, Ohio) interfaced to a computer (MUGA-CART, Medical Data Systems, Ann Arbor, Michigan) was used for image acquisition and data analysis. Images were recorded in 14 frames from the end of diastole through two thirds of the cardiac cycle and approximately 200,000 counts were obtained in each frame.

**Exercise protocol:** Supine exercise studies were performed with a bicycle ergometer table (Engineering Dynamic, Lowell, Massachusetts) during continuous 12-lead electrocardiographic monitoring (Hewlett Packard, Waltham, Massachusetts). Exercise was begun at a pedal speed of 50 rpm and a work load of 150 kpm/min and increased by 150 kpm/min every 3 minutes to a symptom-limited maximum (fatigue, shortness of breath, or angina). Images were obtained in the left anterior oblique projection starting 1 minute after each exercise level was begun and continued until approximately 200,000 counts/frame were acquired (1.5 to 2 minutes). Heart rate and blood pressure were recorded at each exercise level. The maximal heart rate was expressed as a fraction of the predicted maximal heart rate to be anticipated based on patient age (220 minus age). A significant abnormal electrocardiographic response to exercise was ≥1 mm of horizontal S-T segment depression, 0.08 second after the J point.

**Catheterization data:** Each patient underwent routine cardiac catheterization which included right- and left-sided pressure measurements, selective coronary arteriography, and radiographic contrast left ventriculography. Coronary angiograms were reviewed by 2 observers and disagreements settled by consensus. Coronary stenoses were measured using calipers in relation to the proximal normal-appearing segment in 2 or more angiographic projections. Greater than 50% narrowing in any vessel was considered to be significant stenosis.

**Ejection fraction analysis:** EF was determined from the rest and peak exercise left anterior oblique images. A semiautomated edge detection algorithm was used to determine counts within the left ventricular region of interest (Medical Data Systems, MUGE Program). EF was the difference between background-corrected end-diastolic and end-systolic counts divided by end-diastolic counts. EF was reported as the average of 2 separate determinations. Previous data from our laboratory indicate that the intraobserver variability for EF (±2 standard deviations) is ±6% at rest, ±9% with exercise, and ±11% for the change between rest and exercise.[18] In this study, the EF was determined by 1 observer at 2 separate times (2 months apart) without knowledge of clinical or catheterization data or the 2 values averaged.

**Ejection rate analysis:** The average ejection rate was the change in counts in the left ventricle from end-diastole to end-systole with respect to time, normalized for end-diastolic counts (stroke counts/ejection time/end-diastolic counts).[2] Because the counts within the left ventricular region of interest are proportional to volume, this measurement is comparable to the change of volume over time relation normalized for end-diastolic volume which has been obtained from the contrast ventriculogram (dV/dt/end-diastolic volume). Ejection rates were determined by 1 observer on 2 separate occasions without knowledge of clinical or catheterization data and the 2 values averaged.

**Left ventricular volume analysis:** End-diastolic volume was calculated using a previously reported geometric approach.[19,20] This involves (1) calibration of the camera system for actual square centimeters per picture element, (2) computer derivation of the area in square centimeters, (3) computer derivation of the longest chord in centimeters within the left ventricular region of interest, and (4) trigonometric correction to orthogonal biplane views. For this study, the calculation was modified so that end-diastolic volumes were derived from the left anterior oblique view alone, allowing a measurement of end-diastolic volume during rest and peak exercise (without having to change the position of the camera). This was accomplished by using the computer-derived left anterior oblique area and length and the single-plane area-length equation of Sandler and Dodge[21,22]: Volume = 4/3 long axis × short axis$^2$, where short axis = 4 area/$\pi$ long axis.

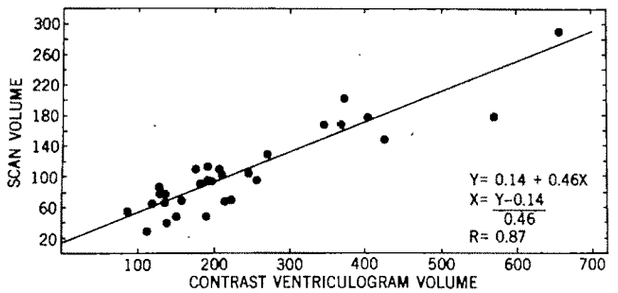

**FIGURE 1.** Linear regression curve of contrast left ventriculographic end-diastolic volume (right anterior oblique) and radionuclide ventriculographic end-diastolic volume (left anterior oblique); Y = scan volume, X = contrast ventriculographic volume. Rearrangement of equation for use in our patient study where scan volumes were measured and related to catheterization volumes (considered true volumes): X = (Y/0.46 − 0.14)/0.46. The standard error of the estimate was 13 ml/m$^2$.

To determine the validity of using this single-plane geometric approach, 30 other patients (7 normal patients and 23 with coronary disease) undergoing both contrast left ventriculography and multigated blood pool scans were analyzed. Left anterior oblique end-diastolic volumes were compared with volumes derived from anterior oblique single-plane left ventriculography and biplane-multigated blood pool scanning. The individual paired data points for right anterior oblique contrast ventriculograms and left anterior oblique multigated blood pool scans are shown in Figure 1. The values correlate closely ($r = 0.87$, $p < 0.0001$). There was also a close correlation between left anterior oblique and biplane-multigated blood pool scan values ($r = 0.91$, $p < 0.0001$). For both correlations, the slope of the regression line was substantially less than unity (left anterior oblique absolute volumes were smaller). This may be partly due to the fact that the left ventricle is more foreshortened in the left anterior oblique compared to the right anterior oblique view. For this study, all scan end-diastolic volumes derived from the gated blood pool scan were corrected to angiographic volume using the regression equation and were then divided by the body surface area to derive an index value.

Stroke volume was calculated as EF multiplied by the end-diastolic volume and cardiac output was stroke volume times heart rate. End-systolic volume was the difference between end-diastolic volume and stroke volume. This approach avoided assuming a left ventricular end-systolic geometry. Volumes were determined by 1 observer on 2 separate occasions without knowledge of clinical or catheterization data, and the 2 results were averaged.

**Peak systolic pressure/end-systolic volume analysis:** Peak systolic pressure was determined by blood pressure cuff at rest and at each stage of exercise. The ratio of peak systolic pressure to end-systolic volume index was calculated as an average of the 2 derived values.[11]

**Pulmonary blood volume ratio:** The ratio of pulmonary blood volume during exercise compared with rest was derived from multigated blood pool scanning. This parameter has been shown of value in differentiating patients with and without CAD.[6] A region of interest was placed over the lung in both rest and exercise end-diastolic images. The count ratio of exercise to rest activity, normalized for study collection time, was calculated. From previous work, a ratio of 1.05 was found to be 2 standard deviations above the normal mean and was defined as the upper limit of normal. Pulmonary blood volume ratios were determined by 2 observers and then averaged.

| Difference | +47 ± 32 | +38 ± 23 | ... |

Values are mean ± 1 standard deviation.
* $p < 0.001$, compared with rest value.

**Statistical analysis:** The differences between rest and exercise values of each variable were derived. Group values were expressed as mean ± 1 standard deviation. Differences among group means were compared using an unpaired $t$ test. Changes between rest and exercise values were compared using a paired $t$ test. Frequency differences were compared using chi-square analysis. A 2-way analysis of variance was performed on the duplicate values for each scan-determined variable which were determined on the 2 occasions. This was done to calculate experimental plus operator error in an attempt to assess the significance of individual differences with respect to random error, which is important when data from individual patients are being considered. However, when group means are used, random error in both directions negates this problem and thus the individual variations may be less important in data analysis.

## Results

**Clinical data (Table I):** Patients with CAD were significantly more frequently male, more likely to be receiving propranolol, and had a lower maximal heart rate and systolic blood pressure with exercise than pa-

* Previously reported.[6,11]

tients without CAD. Within each group, there was no relation between taking propranolol and peak exercise heart rate.

**Intraobserver variability:** The intraobserver variance (±2 standard deviations) for the variables studied are summarized in Table II.

**Overall scan data (Table III):** At rest, patients with CAD could not be differentiated from normal patients. With exercise, EF, ejection rate, and the peak systolic pressure/end-systolic volume ratio were significantly lower and end-systolic volume was significantly higher in patients with CAD than in normal patients. The exercise/rest pulmonary blood volume ratio was greater in patients with CAD. Differences in end-diastolic volume were not statistically significant.

**Scan data in normal patients:** Among the 21 normal patients, EF increased by ≥0.05 during exercise in 13 patients (62%) and failed to increase by 0.05 in 8 patients. The 2 groups of normal patients did not differ in any clinical variable except for peak exercise heart rate. Patients who increased EF by ≥0.05 during exercise had a lower peak heart rate than patients who increased EF by <0.05 (134 ± 24 versus 153 ± 18, p <0.05). Five of the 13 and 3 of the 8 patients in the 2 normal groups were receiving propranolol (difference not significant).

Mean values for scan-derived variables of left ventricular performance are shown in Table IV and illustrated in Figure 2. The 2 groups of normal patients did not differ in any parameter at rest. However, the group with a ≥0.05 increase in EF during exercise accomplished this with a significant increase in stroke volume and a significant decrease in end-systolic volume. On the other hand, the group with a <0.05 increase in EF had no change in stroke volume or end-systolic volume with exercise. The peak exercise values did not differ significantly in the 2 groups except for the peak systolic pressure/end-systolic volume during exercise, which was higher in patients with a ≥0.05 increase in EF.

**Scan data in patients with coronary disease:** Among the 32 patients with CAD, the EF increased by ≥0.05 during exercise in 15 patients (47%) and failed to

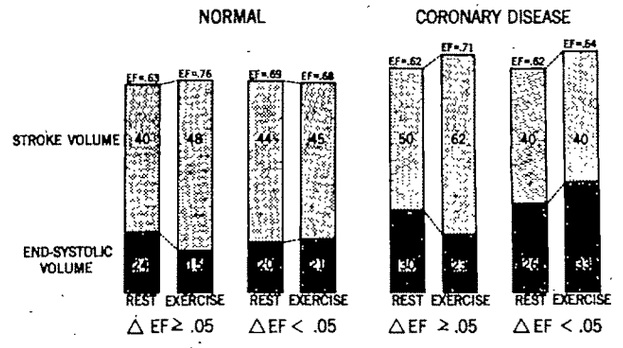

**FIGURE 2.** Mean radionuclide volumes and EF data collected during rest and exercise for normal and CAD patients grouped according to whether EF increased with exercise.

increase by 0.05 in 17 patients. Only 2 of 15 patients (13%) with a normal EF during exercise had a previous myocardial infarction compared with 9 of 17 patients (53%) with an abnormal response to exercise ($p < 0.05$). There was no difference in any other clinical variable, including propranolol use or the number of diseased vessels in either group. Ten of the 15 and 14 of the 17 patients in the 2 coronary disease groups were receiving propranolol (difference not significant). Mean resting heart rate and resting and exercise systolic blood pressure were similar in the 2 coronary disease groups and did not differ significantly from normal. The peak heart rate was comparably reduced in both groups (116 ± 20 and 107 ± 27, difference not significant), which was significantly below the peak heart rate in normals (142 ± 23, $p < 0.01$). The patients with a ≥0.05 increase in EF included 3 with single-vessel left anterior descending disease, 9 with double-vessel disease, and 3 with triple-vessel disease. The patients with a <0.05 increase in EF included 3 with single-vessel left anterior descending disease, 8 with double-vessel disease, and 6 with triple-vessel disease. These distributions did not differ significantly.

The mean values for the scan variables of left ventricular performance in patients with CAD with a ≥0.05 increase versus <0.05 increase in EF are shown in Table V and illustrated in Figure 2. Patients with an increase ≥0.05 in EF demonstrated an increase in ejection rate, stroke volume, and peak systolic pressure/end-systolic volume ratio and a decrease in end-systolic volume during exercise. This group differed significantly from the normal group only in having a lower peak systolic pressure/end-systolic volume ratio during exercise (7.8 ± 2.7 versus 11.8 ± 4.6, $p < 0.01$), and a higher pulmonary blood volume ratio (1.06 ± 0.17 versus 0.99 ± 0.13, $p < 0.05$). Ejection rate, EF end-diastolic volume, stroke volume, end-systolic volume, and cardiac output did not differ significantly from that in the normal group.

Coronary disease patients with an EF increase <0.05 were characterized by a significant increase in end-diastolic and end-systolic volumes during exercise and no change in ejection rate, stroke volume, and the peak systolic pressure/end-systolic volume ratio. These patients did not differ from normal subjects at rest; however, with exercise the heart rate, ejection rate, cardiac index, and peak systolic pressure/end-systolic volume were lower than in normal subjects ($p < 0.01$) and pulmonary blood volume was higher than in normal patients ($p < 0.01$).

* $p < 0.01$, † $p < 0.001$, compared with resting value. Values are mean ± 1 standard deviation. Abbreviations as in Table III.

Among all coronary disease patients, there was no difference in rest or exercise values in patients with and without electrocardiographic ischemia during exercise except for a smaller exercise increase in peak systolic pressure/end-systolic volume ratio in ischemic patients (+0.3 ± 0.8 versus + 2.4 ± 0.6, $p < 0.05$). However, when patients with and without previous myocardial infarction were compared, the 13 patients with previous myocardial infarction had (1) a lower rest and exercise EF (rest = 0.54 ± 0.13 versus 0.67 ± 0.08, $p < 0.05$; exercise = 0.56 ± 0.11 versus 0.66 ± 0.12, $p < 0.05$); (2) a lower rest and exercise stroke volume (ml/m²) (rest = 34 ± 11 versus 50 ± 16, $p < 0.05$; exercise = 39 ± 14 versus 58 ± 25, $p < 0.05$); (3) a lower rest and exercise cardiac output (liters/min/m²) (rest = 2.4 ± 0.7 versus 3.2 ±1.3, $p < 0.05$; exercise = 4.4 ± 1.4 versus 6.4 ± 3.1, $p < 0.05$).

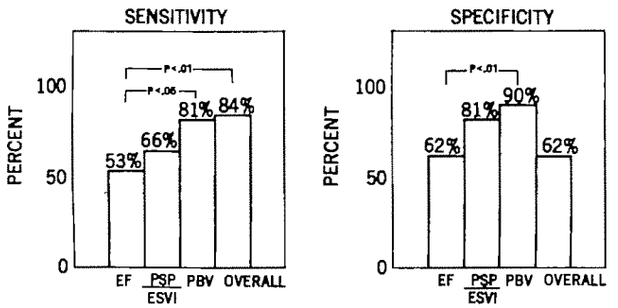

**FIGURE 3.** Comparison of the sensitivities and specificities of EF, peak systolic pressure (PSP)/end-systolic volume (ESVI) ratio, and pulmonary blood volume (PBV) ratio (see text).

**Sensitivity and specificity:** An EF increase during exercise of ≥0.05 had a sensitivity for detecting coronary disease of 53% (17 of 32) and a specificity of 62% (13 of 21). When normal was defined as a peak systolic pressure/end-systolic volume index increase with exercise of ≥2, the sensitivity was higher than for EF, 66% (21 of 32) as was the specificity, 81% (17 of 21). However, these increases did not reach statistical significance. When normal was defined by an exercise/rest pulmonary blood volume ratio of <1.06, the sensitivity increased to 78% (25 of 32), $p < 0.05$, and the specificity increased to 90% (19 of 21), $p < 0.01$. Using peak systolic pressure/end-systolic volume ratio and exercise/rest pulmonary blood volume ratio in conjunction with EF significantly increased overall sensitivity from 53 to 84% (27 of 32), $p < 0.01$, with no change in specificity compared with EF alone (Fig. 3).

## Discussion

Cardiologists have long sought a simple yet accurate method to noninvasively predict the presence or absence of CAD. The development of exercise radionuclide angiography has generated hope that such a method might be available. However, EF is often the only objective parameter of left ventricular function derived by many laboratories performing radionuclide ventriculography, and EF can be influenced by cardiac loading conditions and heart rate and is not purely related to myocardial contractile function.[11,23,24] Optimally, the EF response to exercise would be abnormal in all patients with CAD and normal in patients without CAD. However, the present study demonstrates that the response of EF to exercise was neither sensitive nor specific in differentiating patients with and without significant CAD. One limitation of the present study is the relatively large number of patients receiving propranolol. This was not by design but was related to the reluctance of most physicians at our institution to discontinue propranolol. Although this may contribute to false-positive and false-negative studies,[25,26] this group of patients is likely to be representative of routine patients encountered at many clinical facilities.

In our study, the sensitivity (53%) was considerably lower than previously reported values.[12] This may be explained in part by the fact that many patients in our group had clinically less severe coronary disease (that is, no unstable angina, congestive heart failure, or aneurysms). In addition, most of the coronary patients were receiving propranolol which may have "normalized" the EF during exercise in some patients with CAD.[25,26]

Among the coronary disease patients, 1 subset was strikingly similar to normal patients in that EF increased ≥0.05 during exercise. These patients did differ from normal in having a lower exercise heart rate, peak systolic pressure/end-systolic volume ratio, and a higher pulmonary blood volume ratio. In addition, fewer patients in this group had had a myocardial infarction compared to the remainder of the coronary disease patients. The latter patients (those with an "abnormal" EF response to exercise) with a <0.05 increase in EF with exercise, differed from normal in nearly all parameters studied, which is consistent with data reported in previous studies.[17,25–30]

The relatively low specificity (62%) of the 0.05 increase in EF with exercise in the "normal" population also warrants explanation. All of the patients in this group underwent coronary angiography to evaluate a chest pain syndrome. Such patients may have had disease involving the smaller vessels or the substance of the myocardium even though abnormalities were not evident at rest,[31–33] which might result in a depressed left ventricular reserve as evidenced by a lack of increase in EF during exercise. Alternatively, this observation may be explained by factors other than contractile reserve influencing EF in this group of patients, such as age, high contractile state of the myocardium at rest, abnormal responsiveness of the peripheral vascular system or autonomic nervous system, or both, and altered ventricular loading conditions.[17,31–33] Some patients in this group were receiving propranolol and nitrates, which may affect the EF, although the mean EF response was similar in the patients who were not receiving these agents.

**Quantitation of end-diastolic volume:** Other parameters of potential value in detection of exercise-induced left ventricular dysfunction can be derived from radionuclide cineangiography, and we were interested in determining what further pathophysiologic insight these might provide. To accomplish this goal, it was necessary to measure end-diastolic volume. In our study a geometric approach to derivation of end-diastolic volume was employed,[19,20] although reliable volumes may also be obtained using a counts method.[3,4,7,9,34] Our method has several potential limitations when compared with the "gold standard": biplane contrast left ventriculography. First, for both contrast ventriculography and the blood pool studies, only a single view was used. A single-plane volume analysis may provide misleading data because coronary disease is known to affect left ventricular systolic function regionally, and therefore evaluation of the 2 views would be more desirable than just a single view.[35] Unfortunately, only a single-view contrast ventriculogram during catheterization and a single-view gated scan during exercise was available. Nevertheless, there is ample evidence in the literature that a single-plane geometric assessment of

end-diastolic volume using x-ray contrast left ventriculography is adequate.[21,22] This is because the impact of an intervention on end-diastolic volume alone is likely to be global and similar in different projections. Only changes in systole are likely to be regional. Furthermore, nearly all methods for radionuclide EF and counts-based end-diastolic volume measurements use a single view of the left ventricle.

The second limitation may be the use of a geometric compared with a counts-based method. A previous study suggested that reliable data may be derived using either method with no significant difference in correlation coefficients or standard errors of the estimate.[34] In the previous study, the area-length data were derived primarily from analog (Polaroid®) images, whereas our data were analyzed using digitized images and a computer algorithm to determine area and length. One advantage of the geometric approach is that assumptions about variations in tracer attenuation from activity in basal compared with apical portions of the left ventricle are avoided.[35] Once again, geometric assumptions were used to derive only end-diastolic volume and not EF. End-systolic volume and stroke volume were derived from EF and end-diastolic volume, and no assumptions about the shape or motion of the left ventricle during systole were necessary. Furthermore, no patients with left ventricular aneurysm were included and all but 4 patients had resting EF values >0.50. Therefore, our patients were unlikely to have end-diastolic left ventricular outlines that differed markedly from an ellipsoidal shape, which might be source of error using a geometric estimate of end-diastolic volume.

The third potential limitation is that the single view used to quantitate end-diastolic volumes was the left anterior oblique instead of the more commonly used single-plane right anterior oblique view. Although a right anterior oblique view should be more desirable because more left ventricular wall is exposed,[36] this view is not available using equilibrium blood pool imaging due to superimposition of right ventricular activity. All exercise equilibrium approaches to derive EF or end-diastolic volume utilize the left anterior oblique view alone. For these reasons, our approach to end-diastolic volume measurement appears reasonable, and its accuracy and limitations are comparable to those of other methods.[34]

**Observer variability:** In addition to errors inherent in the methodologic assumptions used to derive the 8 variables evaluated, inconsistency in data may also occur due to observer variability. The present data support previous data from this laboratory[18] indicating that measurement of these variables is complex and has considerable intraobserver variability. Furthermore, the observation that intraobserver variance (±2 standard deviations) for the change in EF from rest to exercise is 0.11 may be partly responsible for some of the apparent inconsistencies between the EF response to exercise and the presence or absence of CAD. The 0.05 increase in EF with exercise criteria may be within the individual error due to observer variability. This probably does not explain the entire inconsistency, however, because the other variables (derived in part from EF) appeared to have less inconsistency. The observer variability leads to difficulties in comparing data from different institutions, and therefore the range of normal used in this study is unlikely to be useful in patients studied elsewhere. However, it is unlikely to present a problem in comparing patient groups in this study because mean values were employed, thereby reducing differences due to individual observer variability and allowing statistical comparison of different groups.

**Other variables measured during exercise:** As with EF, variable responses of ejection rate (dV/dt), cardiac index, and absolute volumes to exercise did not differentiate patients with and without CAD. However, 2 measurements of global left ventricular function, the peak systolic pressure/end-systolic volume ratio response to exercise and pulmonary blood volume (exercise/rest ratio), were consistently different in patients with CAD and normal patients. The pressure/volume ratio, a parameter which may be less influenced by cardiac loading conditions,[11,37–39] showed a smaller increase with exercise in patients with coronary heart disease. The pulmonary blood volume ratio, a parameter which may be related to left ventricular filling pressure,[40] was greater in patients with CAD than in normal patients. The use of these 2 parameters in addition to EF significantly increased sensitivity from 53 to 84% without worsening specificity. Therefore, these parameters appear to be helpful adjuncts to EF in detecting CAD. Our study confirms other reports which indicate that analysis of other aspects of left ventricular function besides EF is useful in defining ventricular performance.

**Clinical implications:** Although the left ventricular EF response to exercise is "abnormal" in many patients with CAD, this parameter alone is not a reliable indicator of coronary disease. Normal patients may not have an increase in EF with exercise and some CAD patients may have an EF increased by ≥0.05. Furthermore, in the present study no parameter of global left ventricular function invariably detected or excluded CAD. Therefore, inferences concerning the presence or absence of CAD from rest and exercise global left ventricular function parameters should be made with caution. This study considered only parameters of global left ventricular function; previous data have shown that the sensitivity and specificity of radionuclide cineangiography as a technique in the evaluation of CAD are considerably improved when regional wall motion is also analyzed.[5,12] Further studies which include regional wall motion (not performed in this study) might even indicate that no additional advantage is gained in terms of sensitivity and specificity with the use of these other parameters. However, in most clinical settings regional wall motion assessment is subjective. This study suggests that objective parameters can be derived from careful analysis of radionuclide images and are helpful in defining cardiac function more precisely, as well as in improving the diagnostic yield of the radionuclide EF.

# Left and Right Ventricular Function at Rest and During Bicycle Exercise in the Supine and Sitting Positions in Normal Subjects and Patients With Coronary Artery Disease

## Assessment by Radionuclide Ventriculography

DANTE E. MANYARI, MD, FRCP(C) and WILLIAM J. KOSTUK, MD, FRCP(C),
*With the technical assistance of* PAUL P. PURVES, RTNM

**To assess the hemodynamic influence of posture during radionuclide cardiac studies, rest and exercise electrocardiographically gated blood pool cardiac scintigraphy was performed in the supine and sitting positions in 22 normal subjects and in 20 patients with coronary artery disease (CAD). In normal subjects, left ventricular ejection fraction was higher in the sitting position both at rest (67 ± 6% versus 64 ± 5%, $p < 0.01$) and during exercise (79 ± 9% versus 76 ± 6%, $p < 0.05$). Left ventricular end-diastolic volume in the sitting position was smaller at rest (by 19 ± 26%, $p < 0.001$), but this variable was similar in both positions during exercise ($p > 0.05$). Left ventricular end-systolic volume was smaller in the sitting position both at rest, by 26 ± 31 percent, and during exercise, by 14 ± 20% ($p < 0.001$). Left ventricular end-diastolic volume increased from rest to exercise, in the sitting position by 31 ± 23% ($p < 0.001$) and in the supine position by 6 ± 22% ($p > 0.05$).**

**In patients with CAD, similar left ventricular ejection fractions in both postures were found at rest and during exercise. Left ventricular end-diastolic volume in the sitting posture was smaller at rest by 16 ± 22% ($p < 0.01$) and during exercise by 8 ± 18% ($p < 0.05$). Sitting left ventricular end-systolic volume was smaller by 18 ± 20% ($p < 0.001$) at rest and by 14 ± 21% ($p < 0.01$) during exercise. Left ventricular end-diastolic volume increased from rest to exercise, in the sitting position by 45 ± 36% ($p < 0.001$) and in the supine position by 32 ± 51% ($p < 0.01$). Despite significant hemodynamic differences, the value of rest-exercise radionuclide cardiac studies to detect CAD was similar in the 2 positions.**

Radionuclide ventriculography is being used extensively as a noninvasive method to assess ventricular function at rest and during exercise in both the supine and the sitting positions.[1–7] In normal subjects, left ventricular ejection fraction increases during bicycle ergometer exercise. In contrast, ejection fraction fails to increase at peak exercise in patients with coronary artery disease.[1–7] Although previous studies have determined the rest and exercise hemodynamic differences between the supine and sitting positions,[8–17] limited information is available regarding comparative scintigraphic studies in the 2 postures.[18–20] Furthermore, the few studies available thus far report conflicting results.

This investigation was undertaken to compare left ventricular ejection fraction and volume patterns and right ventricular ejection fraction, at rest and during bicycle exercise, in both the supine and sitting postures, in subjects without demonstrable heart disease and in patients with angiographic CAD and normal left ventricular function. The electrocardiographically gated blood pool cardiac scintigraphy, a noninvasive technique useful for serial determinations of quantitative ventriculograms,[1–4,19–23] was used.

### Methods

**Patient population:** Twenty-two normal subjects included in the first group consisted of 16 men and 6 women aged 19 to 59 years (mean ± standard deviation 44 ± 12). Fourteen patients had atypical chest pain with normal hemodynamic function and coronary artery anatomy at cardiac catheterization and selective coronary artery cineangiography. No patient had clinical or electrocardiographic evidence of variant angina.[24] The remaining 8 were asymptomatic volunteers without evidence of cardiac disease. All control subjects had normal findings on physical examination, chest X-ray, and resting and exercise electrocardiography. None was an athlete or had performed regular exercise training in the recent or remote past.

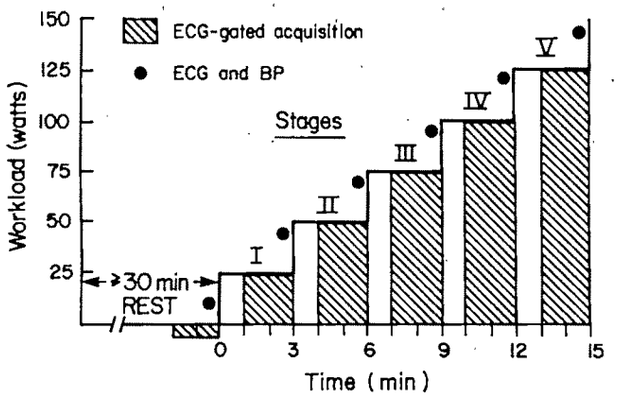

**FIGURE 1.** Exercise protocol. Subjects were often exercised to more than 5 stages. There was a rest period of ≥30 minutes before exercise in the first position, and at least a 60-minute rest period before exercise in the second position. Acquisition was performed twice at rest in each posture immediately before starting exercise. BP = blood pressure; ECG = electrocardiogram.

The second group consisted of 20 patients with CAD, as defined by at least a 50% reduction in diameter of ≥1 major coronary arteries. There were 15 men and 5 women aged 30 to 62 years (mean 47 ± 11). All had stable angina pectoris without evidence of associated cardiac conditions other than coronary heart disease. Patients with a history of acute myocardial infarction, abnormal Q waves (≥40 ms) on the electrocardiogram, or abnormal wall motion on contrast left ventricular cineangiography were excluded. Likewise, patients with valvular heart disease, systemic hypertension, diabetes mellitus, or intermittent claudication were excluded from the study.

All participants were leading a sedentary life, had normal sinus rhythm, and on request, manifested their willingness to participate. Physical examination, except for the occasional patient with an $S_4$ gallop, showed nothing abnormal and none had clinical, electrocardiographic, radiographic, or echocardiographic evidence of cardiomegaly, cardiac failure, left ventricular hypertrophy, or mitral valve prolapse.

Cardiac catheterization, biplane left ventricular angiography, and selective coronary cineangiography, using standard techniques, were carried out within 8 days before the radionuclide study. All participants had normal left ventricular function at rest as determined by an ejection fraction ≥65% on contrast ventriculography or a radionuclide ejection fraction ≥55%, or both, and normal wall motion.

**Radionuclide studies:** Electrocardiographically gated blood pool cardiac imaging was used to assess global and regional ventricular function and volume changes. Each study consisted of 2-minute acquisition in the modified left anterior oblique projection that best separated both ventricles and left atrium. A conventional Anger type scintillation camera with 37 photomultiplier tubes equipped with a high-sensitivity parallel-hole collimator interfaced to a dedicated medical computer system was used. Data were collected in a continuous electrocardiographic synchronized mode with 16 frames spanning the cardiac cycle. With this method, approximately 180,000 to 220,000 counts per frame were obtained. Acquisitions were made at rest and during the last 2 minutes of exercise at each work load (Fig. 1).

After retrieval, the raw data underwent 3-point spatial smoothing and background subtraction. A rectangular region of interest was then placed around the ventricle at end-diastole, taking special care to define the aortic and mitral valve planes and the interventricular septum. The left ventricular time activity curve was then generated by an automated edge-detection program which defined new left ventricular regions of interest for each frame of the composite cardiac cycle. From the time-activity curve, left ventricular ejection fraction was calculated by standard methods.[1–3] Right ventricular ejection fraction was calculated by similar methods but using manually defined right ventricular regions of interest at end-diastole and end-systole.[25] All ejection fraction determinations were performed by a single blinded operator.

Two observers who had no knowledge of the patient's

* = $p < 0.001$, versus rest. EF = left ventricular ejection fraction ×100; WMS = wall motion score.

clinical or angiographic data systematically analyzed regional wall motion in 5 segments—high septal, low septal, inferoapical, posterolateral, and superolateral—by subjective assessment of the endless-loop movie format and static mode[1] and with the aid of computer manipulation of images including the stroke volume image,[7,26] the ejection fraction image,[7] and the superimposition of the end-diastolic and end-systolic isocontours.[27] Each segment was classified as normal, hypokinetic, akinetic, or dyskinetic (scored 0, 1, 2, and 3, respectively). The scores of all segments were then added to obtain a numerical expression of wall motion for each study; this figure was then averaged to the nearest whole number between the 2 observers. In our laboratory, the intra- and interobserver variability of wall motion interpretation had correlation coefficients of 0.97 and 0.92, respectively. Radionuclide wall motion and left ventricular ejection fraction correlated closely with contrast studies.[26] An increase in the right and left ventricular ejection fraction of ≥7% and no change in wall motion score was considered the normal response to exercise.[3] Variations in ejection fraction ≤6% may be attributed to physiologic or statistical noise.

Left ventricular volume changes from rest to exercise were determined for end-diastole and end-systole using the same background-subtracted regions of interest as those utilized to calculate ejection fraction, as follows: Percent volume change = $100 \times [(\text{LVC Ex}/e^{-\lambda t}) - (\text{LVC R})]/\text{LVC R}$, where LVC = normalized (that is, corrected for the actual frame time and the number of processed cycles) left ventricular end-diastolic or end-systolic counts at peak exercise (Ex) or rest (R) (average of the 2 radionuclide studies at rest); and $e^{-\lambda t}$ = general equation for isotope decay where t = absolute time difference (in minutes) between the midpoints of rest and exercise studies and $\lambda$ = decay constant for technetium-99m. A negative value indicates a decrease, whereas a positive one indicates an increase in left ventricular volume from rest to exercise. There was a high degree of correlation between the 2 resting values for left ventricular end-diastolic and end-systolic counts, corrected for background and beats processed, in the supine (r = 0.96) and sitting (r = 0.93) positions.

Similarly, left ventricular volume differences between the 2 postures were calculated for end-diastole and end-systole, both at rest and during peak exercise, as follows: sitting/supine LVV ratio = $100 \times (\text{LVC Sit} \times \text{ID})/(\text{LVC Sup} \times \text{ID})$, where LVV = left ventricular end-diastolic or end-systolic volume; LVC = normalized left ventricular end-diastolic or end-systolic counts at rest or at peak exercise in the sitting (Sit) or supine (Sup) position; ID = correction for isotope decay (ID = 1 for the study performed in the second position and ID = $e^{-\lambda t}$ for the study carried out in the initial position, where t = time [in minutes] between corresponding studies in the supine and sitting positions). An LVV ratio value <100% implies a greater volume supine.

Actual volumes are not measured by this count-derived technique, but because photon attenuation factors such as body build remain constant for each person, relative changes in ventricular volumes produced by exercise and by changes in body position can be compared for each subject. This technique, which has the inherent advantage of making no geometric assumptions about left ventricular shape, has been used to measure left ventricular volume responses to interventions such as exercise, nitroglycerin administration, and atrial and ventricular pacing.[19–23]

**Study design:** Before the investigation was begun, the administration of beta-blocking agents and oral nitrates was discontinued for at least 72 and 24 hours, respectively, in patients receiving these medications. None took sublingual glyceryl trinitrate in the last 6 hours before or during the study.

Studies were carried out at rest and during bicycle exercise in both the supine and the sitting positions, following the protocol depicted in Figure 1. A rest period of 30 minutes preceded the first radionuclide acquisition, and a 60 minute rest period was interspaced between the 2 exercise tests. The order of the position was alternated in consecutive subjects,

so that one half the control subjects and one half the patients with CAD exercised first in the supine position, the other half exercised first in the sitting position. During supine exercise, the ergometer was positioned at the foot of a horizontal table, the axle being 34 cm (13.4 inches) above the table. All participants were exercised to maximal capacity, that is, angina or exhaustion. Symptoms, cuff-blood pressure, and a 9-lead electrocardiogram (standard, limb, and precordial $V_1$ and modified $V_5$ and $V_6$ leads) were recorded throughout the investigation.

**Statistical analysis:** All rest values in a given subject were defined as the average of the 2 resting radionuclide studies. Ejection fraction, heart rate, and blood pressure changes were analyzed by 2-way analysis of variance followed by the Tuckey test when appropriate. Student's $t$ test for paired data was used to compare results, including volume changes induced by exercise, in the supine and sitting positions. To compare the data at a given stage between the 2 groups, the unpaired student's $t$ test was utilized. To determine the statistical significance of sitting to supine left ventricular volume ratio, group values were analyzed with a 2-sided 1-sample $t$ test, where the hypothetical mean equals 100. Results are given as mean ± standard deviation.

## Results

**Normal subjects:** In no subject in this group did angina or an abnormal electrocardiogram develop during or after exercise. At rest, there were no significant differences in heart rate, rate-pressure product, right ventricular ejection fraction, or systolic blood pressure between the 2 postures although the first 3 variables were somewhat higher in the sitting position; however, mean left ventricular ejection fraction was significantly higher in the sitting position (Table I). On exercise in the sitting position, heart rate, rate-pressure product, and left ventricular ejection fraction were significantly higher and systolic blood pressure lower than in the supine position. The difference of right ventricular ejection fraction between the 2 postures did not reach statistical significance.

For both postures there was a significant increase, from rest to peak exercise, in mean heart rate, systolic blood pressure, rate-pressure product, and right and left ventricular ejection fraction ($p < 0.001$). All subjects but 1 in each position had an increase in right ventricular ejection fraction of ≥7%.

Individual and group left ventricular ejection fractions and segmental wall motion scores are shown in Table II. The mean ejection fraction increased on exercise by 12.7% (±7.0) in the supine position, with 20 of the 22 subjects having an increase of ≥7%. In the sitting position, ejection fraction increased during exercise by a mean of 11.8% (±7.2), with 19 subjects having an increase of ≥7%. In 21 subjects the left ventricular ejection fraction response to exercise was concordant in the 2 postures. As per our protocol, all subjects had normal wall motion scores at rest, and in no individual did wall motion score change with body position. During exercise 1 subject supine and 2 sitting had abnormal segmental wall motion scores, concordance being present in 21.

When ejection fraction plus wall motion scores were taken into consideration, discordant results were present in only 1 of the 22 subjects with 2 classified as "abnormal" in the supine (1 man and 1 woman) and 3 in the sitting position (1 man and 2 women).

The mean exercise duration was longer by 0.8 minutes in the sitting position, but this difference was not statistically significant.

**Patients with CAD:** Coronary cineangiography demonstrated single-vessel disease in 7, 2-vessel disease in 6, and 3-vessel disease in 7 patients. Angina developed at peak exercise in 13 patients in the supine and in 11 patients in the upright position. Nine patients in the supine and 10 in the upright position had abnormal S-T segment depression at peak exercise (Table III).

At rest, there were no significant differences in mean heart rate, systolic blood pressure, rate-pressure product, or right and left ventricular ejection fraction between the 2 postures (Table I). In both positions, mean heart rate, systolic blood pressure, rate-pressure product, and right ventricular ejection fraction increased ($p < 0.001$) from rest to peak exercise whereas left ventricular ejection fraction did not. Twelve patients in the supine and 13 in the upright posture had an increase in the right ventricular ejection fraction by ≥7%, concordance being present in 17 patients. During exercise, mean heart rate and rate-pressure product were higher in the sitting than in the supine position. Postural differences in exercise systolic blood pressure and exercise right ventricular ejection fraction did not reach statistical significance (Table I).

Individual and group left ventricular ejection fraction and segmental wall motion scores are presented in Table III. The mean ejection fraction decreased by 2.1% (±8.7) in the supine position, with 17 of the 20 patients failing to have an increase of ≥7%, whereas in the sitting position, ejection fraction decreased by a mean of 1.1% (±8.9), with 17 patients failing to have an increase of ≥7%. In 18 patients, left ventricular ejection fraction response to exercise was concordant in the 2 postures. Mean wall motion scores were similar in both positions at rest and during exercise, with 17 patients showing concordant results. When both ejection fraction plus wall motion scores were taken into consideration, concordance was present in 17 of the 20 patients, with 2 classified as "normal" in the supine and 3 in the sitting position.

**TABLE IV Prediction of the Extent of CAD by Radionuclide Exercise Studies**

| Radionuclide Studies | Coronary Arteriography | | |
|---|---|---|---|
| | No Disease (14) | SVD (7) | MVD (13) |
| Supine | | | |
| No disease | 13 | 1 | 1 |
| SVD | 1 | 3 | 4 |
| MVD | 0 | 3 | 8 |
| Sitting | | | |
| No disease | 12 | 2 | 1 |
| SVD | 2 | 2 | 5 |
| MVD | 0 | 3 | 7 |

MVD = multiple-vessel disease; SVD = single-vessel disease.

Mean exercise duration was 0.6 minutes longer in the sitting posture, but this difference did not reach statistical significance (Table I). However, exercise duration computed for all 42 participants was 8.6 minutes (±3.6) in the supine and 9.4 minutes (±3.6) in the sitting position, the difference being significant at the 1% level.

Details regarding the prediction of the extent of CAD are shown in Table IV in the 34 patients who underwent invasive studies. A correct prediction was made in 24 patients during supine radionuclide studies and in 21 during studies in the sitting position. The presence or absence of CAD was correctly predicted in 31 patients in the supine and in 29 patients in the sitting position.

**Relative left ventricular volume changes during exercise:** In normal subjects exercise-induced changes in left ventricular end-diastolic and end-systolic volumes were significantly different in the 2 postures (Table I). End-diastolic volume increased by 6% in the supine and by 31% in the sitting position, but only in the latter was this increase statistically significant ($p < 0.001$). End-systolic volume decreased in both postures ($p < 0.001$). In patients with CAD (Table I), exercise produced a significant increase ($p < 0.001$) in left ventricular end-diastolic and end-systolic volumes in the 2 positions.

**Relative volume differences between the 2 positions:** Left ventricular end-diastolic volume (Table V) was smaller in the sitting posture at rest in both normal subjects and patients with CAD. During peak exercise, patients with CAD had a smaller end-diastolic volume in the sitting position, whereas normal subjects showed similar end-diastolic volumes in the 2 positions. Left ventricular end-systolic volume (Table V) was significantly smaller in the sitting position in both groups at rest as well as during peak exercise.

## Discussion

Blood pool cardiac scintigraphy at rest and during exercise was carried out in both the supine and the sitting positions in normal subjects and in patients with CAD. The results indicated that (1) the usefulness of rest-exercise radionuclide studies in detecting subjects with CAD is similar in both postures; (2) in patients with CAD left ventricular end-diastolic volume increased from rest to exercise in both positions; (3) in normal subjects left ventricular end-diastolic volume increased from rest to exercise in the sitting but not in the supine

* = $p < 0.001$; † = $p < 0.01$; ‡ = $p < 0.05$.
Ex = peak exercise; LVEDV = left ventricular end-diastolic volume; LVESV = left ventricular end-systolic volume; Sit = sitting; Sup = supine.

posture; (4) at rest, sitting left ventricular end-diastolic and end-systolic volumes were smaller than those supine in both groups; and (5) during exercise, sitting left ventricular end-systolic volume in both groups and sitting end-diastolic volume in patients with CAD were smaller than those supine, whereas end-diastolic volumes in normal subjects were similar in the 2 postures.

**Effect of posture on left ventricular function:** In normal subjects, the higher sitting left ventricular ejection fraction at rest and during exercise found in the present study may represent an increased contractile state (relative to that in the supine position) to compensate for the smaller sitting left ventricular end-diastolic volume. We thus concur with Poliner et al,[18] who suggested that changes in myocardial contractility are of greater relative importance in the upright than in the supine position. Our results are at variance with those of Freeman et al,[20] who reported that exercise left ventricular ejection fraction was similar in the 2 positions. Because the methods used were similar, this discrepancy may be attributable to different study populations.

Previous reports[5] have suggested that "abnormal" left ventricular function response to exercise may be found more frequently in normal women than in normal men. It is thus of interest that 2 of the 3 "abnormal" responses in our group of normal subjects were in women. However, because of the small number of subjects tested, no statistically valid conclusions regarding sex differences can be drawn from our data.

In patients with CAD, left ventricular ejection fraction and segmental wall motion score, at rest and during exercise, were similar in both positions. Therefore, for diagnostic purposes, upright and supine rest-exercise radionuclide ventriculography were equally effective in detecting subjects with CAD and in predicting its extent. These findings agree with those reported by Freeman et al.[20] Despite this generalization, individual variations of more than 6% between left ventricular ejection fraction in 1 position and the other do occur (Tables II and III), which suggest that during longitudinal follow-up radionuclide studies only 1 position should be used throughout.

Patients with electrocardiographic signs of myocardial ischemia during exercise more often developed an abnormal left ventricular function response, whereas all patients with "normal" ejection fraction and wall motion response to exercise showed no electrocardiographic signs of myocardial ischemia (Table III). These observations are in keeping with previous reports.[5,6]

**Effect of posture on left ventricular volume:** Two major physiologic effects of changes in body position are alterations in systemic venous return and in the sympathetic-parasympathetic predominancy.[28,29] A greater effect of posture on left ventricular volume at rest than during exercise is therefore expected because both venous return and sympathetic tone are markedly enhanced by muscular exercise itself,[28,29] regardless of body position. Indeed, our results and those of previous studies[8,18] showed that resting end-diastolic volume in both groups was lower in the sitting than in the supine position.

The smaller sitting left ventricular end-diastolic volume during exercise in patients with CAD may allow them to achieve a higher rate-pressure product in this position. Thus, at peak exercise patients with CAD achieved a similar level of left ventricular stress in the 2 positions. Freeman et al[20] did not compare rest or exercise left ventricular volumes in the 2 postures, but indirect observations led them to postulate a similar hypothesis. Thadani et al[9] found that left ventricular end-diastolic pressure during exercise-induced myocardial ischemia was lower in the upright than in the supine position, and attributed their findings to a relatively lower sitting left ventricular end-diastolic volume. Our results confirm their assumptions.

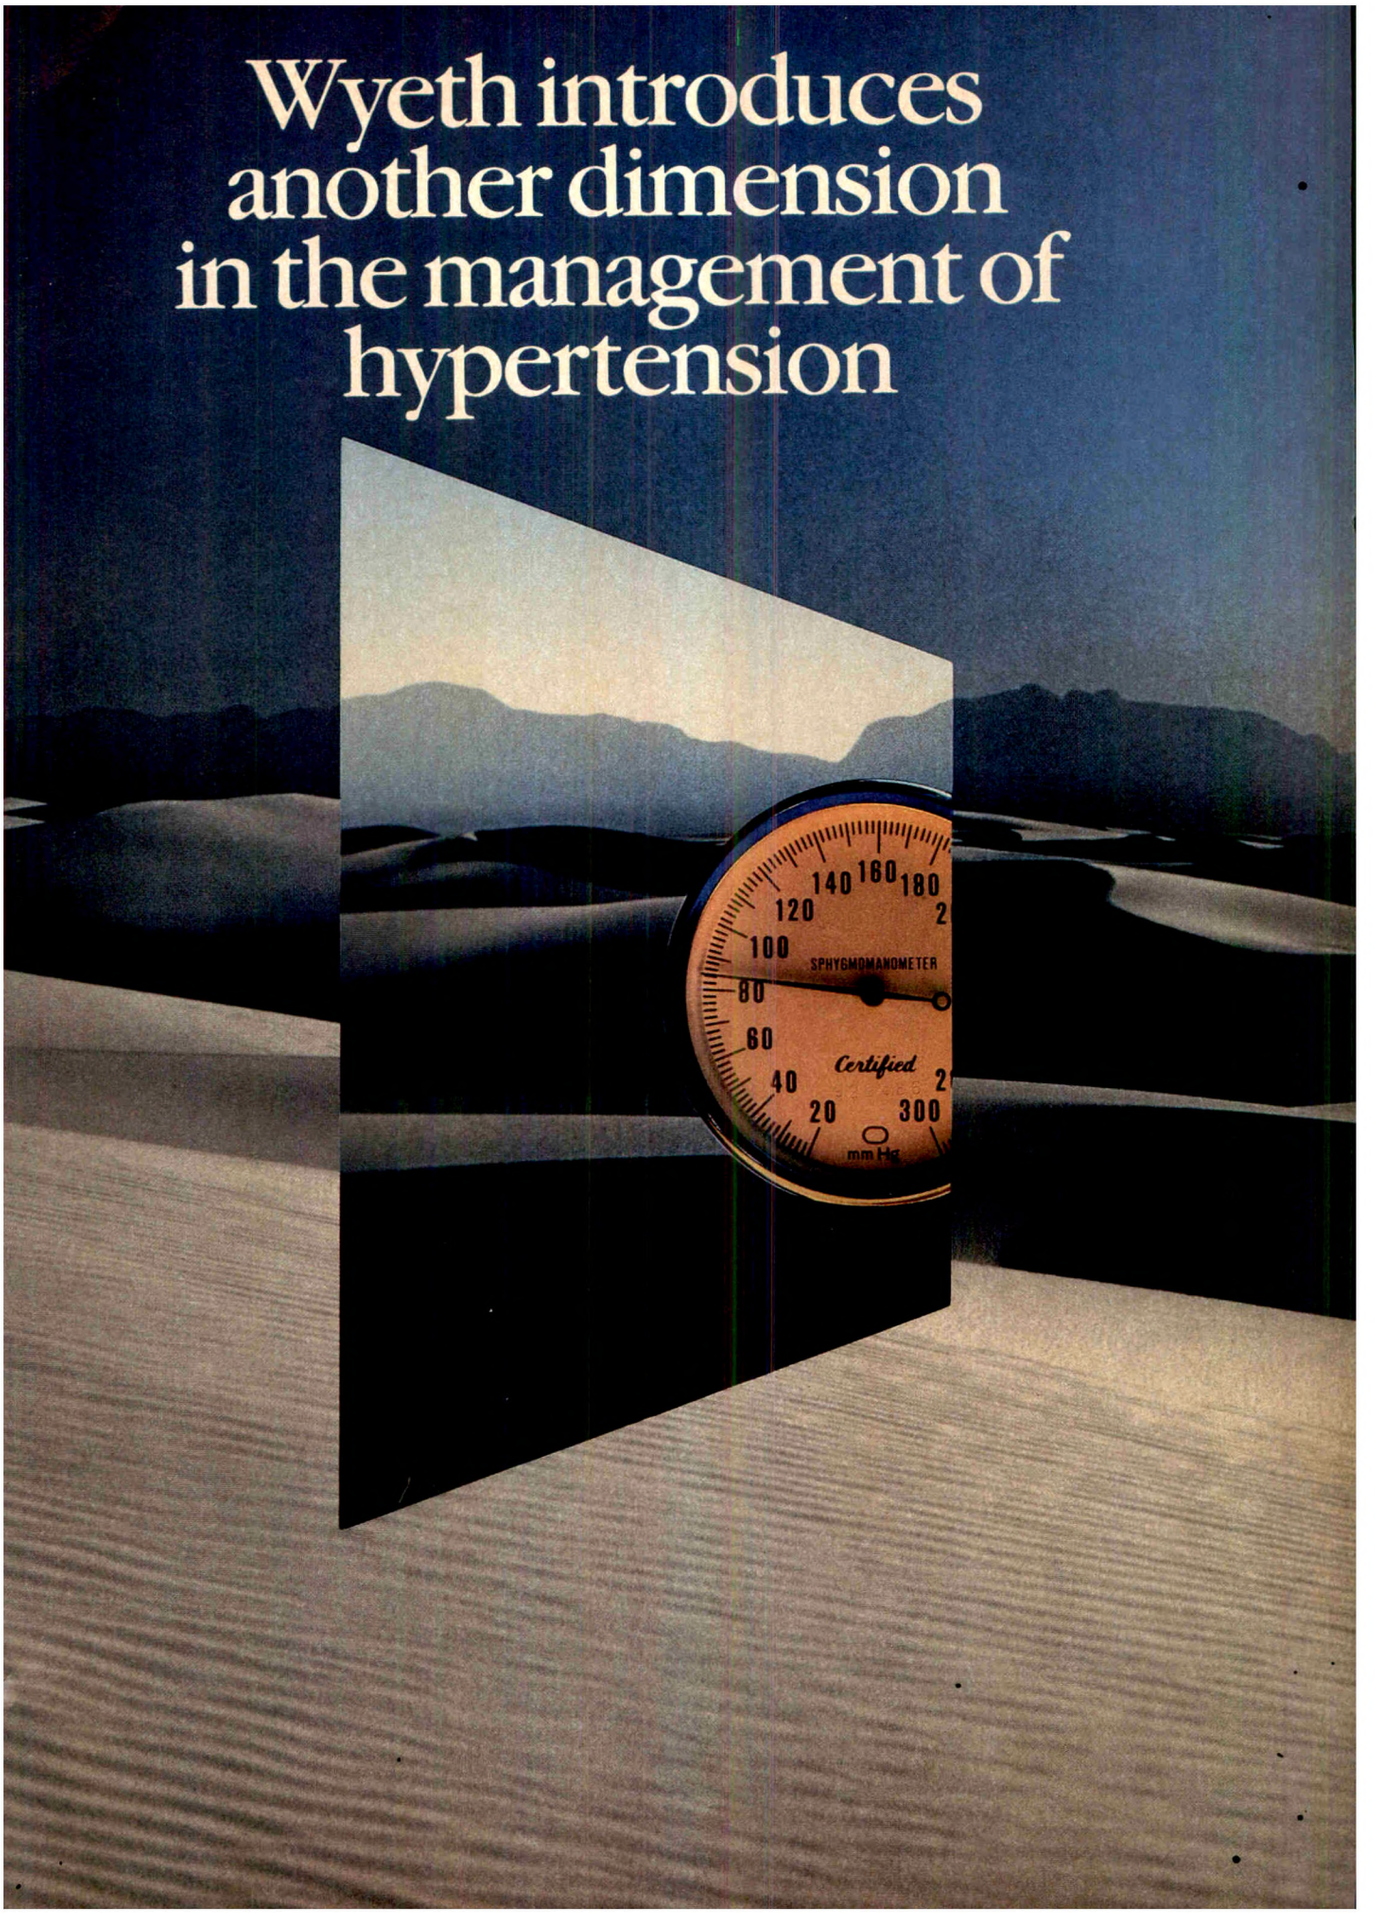
The sitting/supine left ventricular end-systolic volume ratio at rest was smaller in normal subjects than in patients with CAD despite similar sitting/supine end-diastolic volume ratios. These observations suggest that an increased contractility as a response to the diminished venous return in the sitting posture is present only in normal subjects and not in patients with CAD. This inability to increase myocardial contractility may be secondary to their limited oxygen supply, although an altered sympathetic-parasympathetic response cannot be discarded.

**Effect of exercise on left ventricular volume:** End-diastolic volume in normal subjects did not change significantly from rest to exercise in the supine position, but it increased when they exercised in the sitting position. These results reflect a lack of utilization of the Frank-Starling mechanism during exercise in the supine position and the use of this mechanism during upright exercise. Our observations further support the remarks made by Parker and Case[30] who, based on invasive studies, concluded that normal subjects do not make use of the Frank-Starling mechanism when exercising in the supine posture. These findings are in keeping with some previous studies[8,11,20,21,30–32] but not with others.[4,18] In patients with CAD, end-diastolic volume increased from rest to exercise in both positions, implying that the Frank-Starling mechanism was operational in the 2 postures. Similar findings were reported by some[4,20,21] but not by other[31] investigators.

It is difficult to reconcile the disparate reported results regarding exercise-induced ventricular volume changes. Different study populations or leg position may in part account for them. The level of physical conditioning, age, or other factors[33–36] may render physiologically heterogeneous a group of seemingly homogeneous individuals. Weiss et al[37] showed that normal subjects have an increase in left ventricular end-diastolic diameter from rest to exercise in the semisupine position. They attributed those findings to the higher intensity of exertion attained by their participants, but body position may have been the most important factor. In our study the legs were elevated relative to the chest. Poliner et al[18] and Slutsky et al,[31] whose findings were not entirely concordant with ours, did not specify the position of the legs during supine studies.

Finally, despite these generalizations, the effects of both posture and exercise over left ventricular end-diastolic and end-systolic volumes cannot be predicted in the individual subject. Some participants showed no

changes or changes in the opposite direction to those given by the group mean. These observations are not surprising. During invasive studies Thadani et al[9,10,16] and others[38–42] made similar observations and described marked individual variations in left ventricular end-diastolic pressure, stroke index, and stroke work index during exercise. Left ventricular end-diastolic pressure changes may possibly correlate with changes in left ventricular end-diastolic volume. Further studies combining invasive and radionuclide methods will be needed to assess this possibility.



**Implications:** Despite significant differences between the hemodynamic responses at rest and during exercise in the sitting and supine positions, the usefulness of rest-exercise radionuclide studies in detecting subjects with CAD is similar in both postures. Our results suggest that during longitudinal studies, absolute values of quantitative radionuclide ventriculography in 1 position should not be compared with those in the other position either at rest or during peak exercise in the individual patient. In patients with CAD, estimated variables of myocardial oxygen consumption at peak exercise indicate similar metabolic demands in both postures, with the heart rate being higher in the sitting position and the end-diastolic volume being higher in the supine position. Finally, our data support the proposition that during supine exercise normal subjects do not use the Frank-Starling mechanism, whereas this mechanism is evident in patients with CAD during supine exercise and in both groups during upright exercise.

**Acknowledgment:** We are indebted to Mary Collier and Sue Denyar for their secretarial assistance and to Brenda Mullinger for revision of the manuscript.

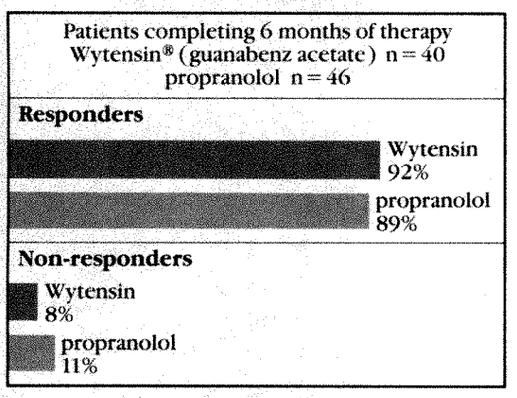
# Wyeth introduces another dimension in the management of hypertension

In clinical trials to date:



- no potassium depletion
- no volume depletion
- no hyperlipidemia
- no hyperuricemia
- no hypercalcemia
- no acid-base disturbances
- no increased renin activity
- no increased catecholamines
- no azotemia
- no hyperglycemia

Wyeth

# Another dimension of management beyond the scope of beta-blockers

**Highly effective in double-blind, multicenter studies**

**Important homeostatic advantages**

| | Wytensin | propranolol |
|---|---|---|
| potassium | — | ↑ |
| serum cholesterol | ↓ | — |
| cardiac output | — | ↓ |
| glomerular filtration rate | — | ↓ |
| peripheral resistance | ↓ | ↑ |
| exercise tolerance | — | ↓ |
| plasma catecholamines | ↓ | ↑ |

**Wytensin® lacks the risks of beta-blockade.**
Wytensin® is less problematic than beta-blockers, which are contraindicated in many patients and must be used with caution in many others. For instance, exercise intolerance, nightmares, and memory failure can be problems with beta-blockers, and in many black and/or elderly patients, beta-blockade is ineffective.

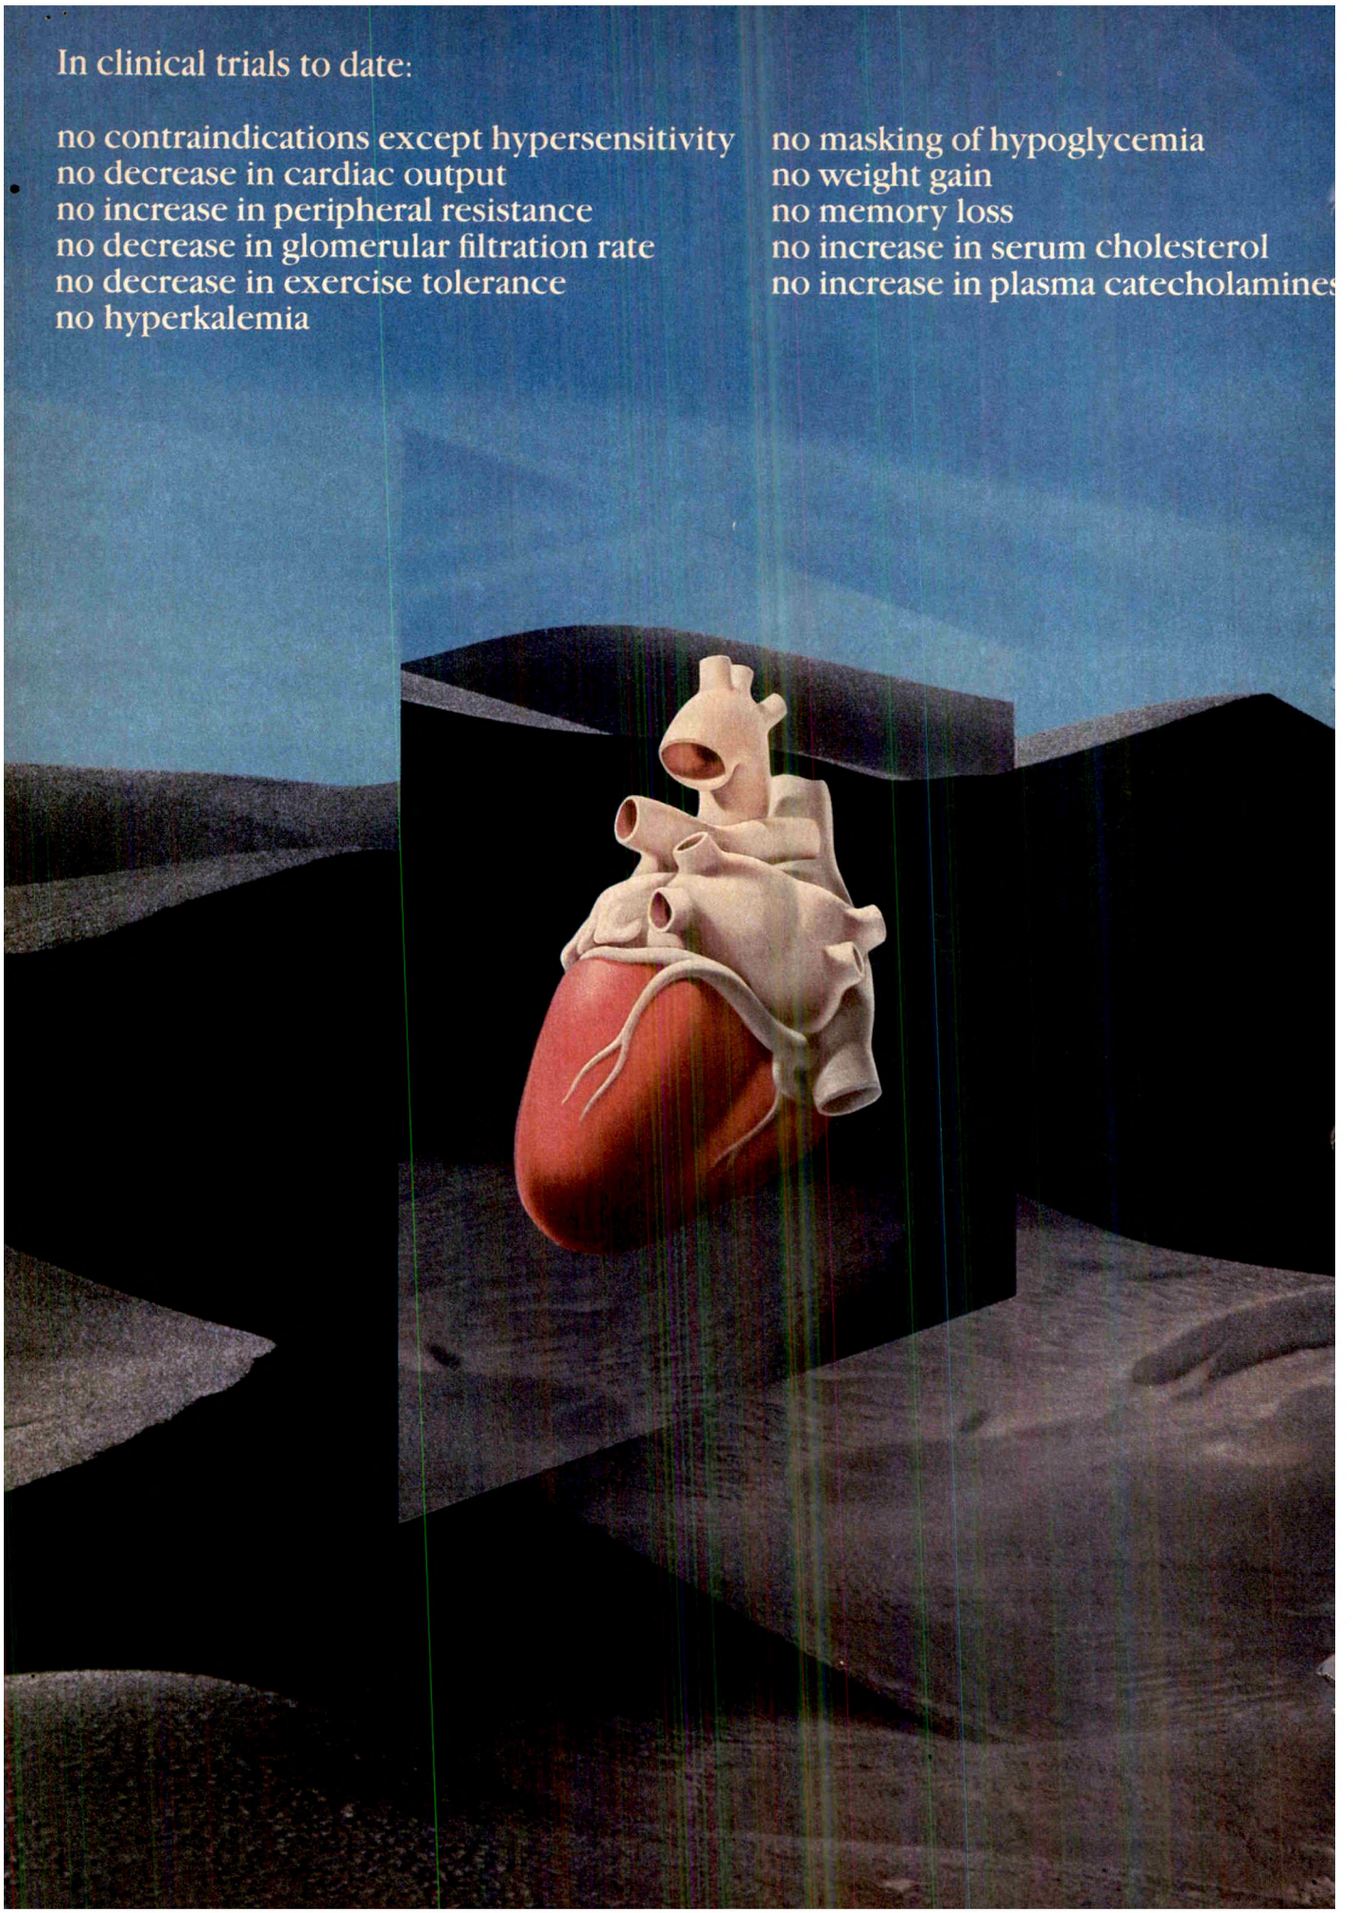
**Wytensin® side effects are usually mild and transient.**
The subjective complaints of drowsiness and dry mouth were the most frequently noted side effects and usually diminished or disappeared over time. During initial therapy, patients should be cautioned against driving automobiles or operating dangerous machinery.

**Wytensin® can be used in a broader spectrum of hypertensives.**
In contrast to beta-blockers, Wytensin has no contraindications except hypersensitivity and is effective regardless of the aging process or racial factors. And, unlike beta-blockers, Wytensin causes a slight decrease in serum cholesterol and maintains potassium balance. Moreover, Wytensin does not cause clinically significant bradycardia or decreased cardiac output. There is no stimulation of vasopressor mechanisms.[2]

New

**WyTensin®**

(guanabenz acetate)

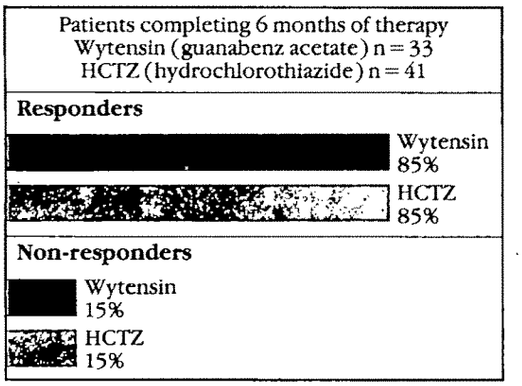


4 mg b.i.d.

Initial monotherapy in hypertension

See important information on last page.

In clinical trials to date:



no contraindications except hypersensitivity
no decrease in cardiac output
no increase in peripheral resistance
no decrease in glomerular filtration rate
no decrease in exercise tolerance
no hyperkalemia
no masking of hypoglycemia
no weight gain
no memory loss
no increase in serum cholesterol
no increase in plasma catecholamines

Wyeth

# Another dimension of management beyond the scope of diuretics

**Highly effective in double-blind, multicenter studies**

**Important homeostatic advantages**

| | Wytensin | HCTZ |
|---|---|---|
| potassium | — | ↓ |
| renin | — | ↑ |
| glucose | — | ↑ |
| serum cholesterol | ↓ | ↑ |
| chloride | — | ↓ |
| uric acid | — | ↑ |
| calcium | — | ↑ |
| BUN | — | ↑ |

**Wytensin® did not induce long-term cardiovascular risk factors.[1]**
Unlike diuretics, Wytensin can be used over the long-term without inducing atherogenic potential risk factors such as hyperlipidemia and hyperglycemia or arrhythmic risk factors such as hypokalemia. With Wytensin therapy a small decrease in heart rate and weight has been observed.

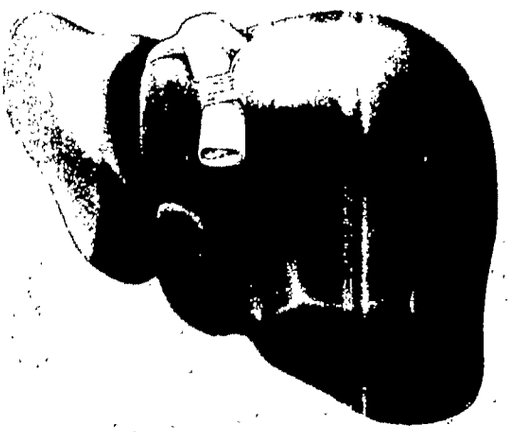
**Wytensin® side effects are usually mild and transient.**
Although dry mouth and/or drowsiness were the most frequently noted side effects, these subjective complaints usually diminished or disappeared over time. Only 9% of patients discontinued therapy due to drowsiness or dry mouth.
About one third of patients who started Wytensin therapy with 8 mg twice daily experienced these side effects, but starting with 4 mg b.i.d.—the recommended starting dose—reduced both the incidence of these side effects and the consequent dropout rate. In all studies to date, discontinuance of therapy for all side effects occurred in about 15% of patients.

**Wytensin® may lower the price the patient pays for therapy.**
Because Wytensin did not induce electrolyte and metabolic imbalance, it may save patients trouble and money. A Wytensin prescription reduces the need for frequent laboratory testing as well as for K-sparing agents or K supplements and other agents that frequently cost more than diuretics alone.

New

**WyTensin®**

(guanabenz acetate)



4 mg b.i.d.

Initial monotherapy in hypertension

| no decrease in GFR | no hemolytic anemia |

Wyeth

# Another dimension of management beyond the scope of methyldopa

**Highly effective in double-blind, multicenter studies**

**Important homeostatic advantages**

| | Wytensin | methyldopa |
|---|---|---|
| sodium excretion | ▬ | ⬇ |
| plasma volume | ▬ | ⬆ |
| weight | ⬇ | ⬆ |
| glomerular filtration rate | ▬ | ⬇ |

**Wytensin® does not produce sodium retention or volume expansion.**[3]
Methyldopa causes sodium retention and volume expansion with consequent development of drug tolerance. In contrast, drug tolerance has not developed with Wytensin probably because it does not induce retention of sodium and body fluid.

**Wytensin® is virtually free of serious adverse reactions.**
Unlike methyldopa, Wytensin does not produce immunological blood or liver toxicity or produce a positive Coombs' test. Wytensin also lacks the relatively high incidence of sexual dysfunction or mental depression seen with methyldopa.

**Wytensin® side effects are often transient or avoidable.**
Patients may experience drowsiness and dry mouth early during Wytensin therapy, but these effects are mostly mild, especially when the initial dosage is 4 mg b.i.d., with the second dose administered **h.s.**

New

**WyTensin®**

# New Wytensin (guanabenz acetate) 4 mg b.i.d.

More than 1,400 patients evaluated
No sodium retention
No electrolyte or metabolic risk factors
A favorable therapeutic index
Convenient, compliance-enhancing b.i.d. dosage
No contraindications except hypersensitivity

**Description**

Wytensin (guanabenz acetate), an antihypertensive agent for oral administration, is an aminoguanidine derivative, 2,6-dichlorobenzylideneaminoguanidine acetate, and its structural formula is:

It is an odorless, white to off-white, crystalline substance, sparingly soluble in water and soluble in alcohol, with a molecular weight of 291.14. Each tablet of Wytensin is equivalent to 4 mg or 8 mg of free guanabenz base.

Wytensin is available as 4 or 8 mg tablets for oral administration.

**Clinical Pharmacology**

Wytensin is an orally active central alpha-2 adrenergic agonist. Its antihypertensive action appears to be mediated via stimulation of central alpha adrenergic receptors, resulting in a decrease of sympathetic outflow from the brain at the bulbar level to the peripheral circulatory system.

PHARMACOKINETICS

In human studies, about 75% of an orally administered dose of Wytensin is absorbed and metabolized with less than 1% of unchanged drug recovered from the urine. Peak plasma concentrations of unchanged drug occur between two and five hours after a single oral dose. The average half-life for Wytensin is about 6 hours. The site or sites of metabolism of Wytensin and the consequences of renal or hepatic insufficiency on excretion of Wytensin or its metabolites have not been determined. The effect of meals on the absorption of Wytensin has not been studied.

PHARMACODYNAMICS

The onset of the antihypertensive action of Wytensin begins within 60 minutes after a single oral dose and reaches a peak effect within two to four hours. The effect of an acute single dose is reduced appreciably six to eight hours after administration, and blood pressure approaches baseline values within 12 hours of administration.

The acute antihypertensive effect of Wytensin occurs without major changes in peripheral resistance, but its chronic effect appears to be a decrease in peripheral resistance. A decrease in blood pressure is seen in both the supine and standing positions without alterations of normal postural mechanisms, so that postural hypotension has not been observed. Wytensin decreases pulse rate by about 5 beats per minute. Cardiac output and left ventricular ejection fraction are unchanged during long-term therapy.

With effective control of blood pressure in hypertensive patients, Wytensin has not demonstrated any significant effect on glomerular filtration rate, renal blood flow, renal sodium or potassium excretion, renal concentrating ability, body fluid volume, or body weight. In clinical trials of six to thirty months, hypertensive patients whose blood pressure was controlled with Wytensin lost one to four pounds of body weight. The mechanism of this weight loss has not been established. Tolerance to the antihypertensive effect of Wytensin has not been observed.

During long-term administration of Wytensin, there is a small decrease in serum cholesterol and total triglycerides without any change in the high-density lipoprotein fraction. Plasma norepinephrine, serum dopamine beta-hydroxylase, and plasma renin activity are decreased during chronic administration of Wytensin. No changes in serum electrolytes, uric acid, blood-urea nitrogen, calcium, or glucose have been observed.

Wytensin and hydrochlorothiazide have been shown to have at least partially additive effects in patients not responding adequately to either drug alone.

**Indications and Usage**

Wytensin is indicated in the treatment of hypertension. It may be employed alone or in combination with a thiazide diuretic.

**Contraindication**

Wytensin is contraindicated in patients with a known sensitivity to the drug.

**Precautions**

1. Sedation: Wytensin causes sedation or drowsiness in a large fraction of patients. When Wytensin is used with centrally active depressants, such as phenothiazines, barbiturates, and benzodiazepines, the potential for additive sedative effects should be considered.

2. Patients with vascular insufficiency: Wytensin, like other antihypertensive agents, should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease, or severe hepatic or renal failure.

3. Rebound: Sudden cessation of therapy with central alpha agonists like Wytensin may rarely result in "overshoot" hypertension and more commonly produces an increase in serum catecholamines and subjective symptomatology.

INFORMATION FOR PATIENTS

Patients who receive Wytensin should be advised to exercise caution when operating dangerous machinery or driving motor vehicles until it is determined that they do not become drowsy or dizzy from the medication. Patients should be warned that their tolerance for alcohol and other CNS depressants may be diminished. Patients should be advised not to discontinue therapy abruptly.

LABORATORY TESTS

In clinical trials, no clinically significant laboratory test abnormalities were identified during either acute or chronic therapy with Wytensin. Tests carried out included CBC, urinalysis, electrolytes, SGOT, bilirubin, alkaline phosphatase, uric acid, BUN, creatinine, glucose, calcium, phosphorus, total protein, and Coombs' test. During long-term administration of Wytensin, there was a small decrease in serum cholesterol and total triglycerides without any change in the high-density lipoprotein fraction. In rare instances an occasional non-progressive increase in liver enzymes has been observed. However, no clinical evidence of hepatic disease has been found.

DRUG INTERACTIONS

Wytensin has not been demonstrated to cause any drug interactions when administered with other drugs, such as digitalis, diuretics, analgesics, anxiolytics, and antiinflammatory or antiinfective agents, in clinical trials. However, the potential for increased sedation when Wytensin is administered concomitantly with CNS depressant drugs should be noted.

DRUG/LABORATORY TEST INTERACTIONS

No laboratory test abnormalities were identified with the use of Wytensin.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY

No evidence of carcinogenic potential emerged in rats during a two-year oral study with Wytensin at doses up to 9.5 mg/kg/day, i.e., about 10 times the maximum recommended human dose. In the Salmonella microsome mutagenicity (Ames) test system, Wytensin at 200-500 mcg per plate or at 30-50 mcg/ml in suspension gave dose-related increases in the number of mutants in one (TA 1537) of five *Salmonella typhimurium* strains with or without inclusion of rat liver microsomes. No mutagenic activity was seen at doses up to those which inhibit growth in the eukaryotic microorganism, *Schizosaccharomyces pombe*, or in Chinese hamster ovary cells at doses up to those which were lethal to the cells in culture. In another eukaryotic system, *Saccharomyces cerevisiae*, Wytensin produced no activity in an assay measuring induction of repairable DNA damage. Reproductive studies showed a decreased pregnancy rate in rats administered high oral doses (9.6 mg/kg) of Wytensin, suggesting an impairment of fertility. The fertility of treated males (9.6 mg/kg) may also have been affected, as suggested by the decreased pregnancy rate of their mates, even though the females received Wytensin only during the last third of pregnancy.

PREGNANCY

Pregnancy Category C

WYTENSIN MAY HAVE ADVERSE EFFECTS ON THE FETUS WHEN ADMINISTERED TO PREGNANT WOMEN. A teratology study in mice has indicated a possible increase in skeletal abnormalities when Wytensin is given orally at doses of 3 to 6 times the maximum recommended human dose of 1.0 mg/kg. These abnormalities, principally costal and vertebral, were not noted in similar studies in rats and rabbits. However, increased fetal loss has been observed after oral Wytensin administration to pregnant rats (14 mg/kg) and rabbits (20 mg/kg). Reproductive studies of Wytensin in rats have shown slightly decreased live-birth indices, decreased fetal survival rate, and decreased pup body weight at oral doses of 6.4 and 9.6 mg/kg. There are no adequate, well-controlled studies in pregnant women. Wytensin should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

NURSING MOTHERS

Because no information is available on the excretion of Wytensin in human milk, it should not be administered to nursing mothers.

PEDIATRIC USE

The safety and effectiveness of Wytensin in children less than 12 years of age have not been demonstrated. Therefore, its use in this age group cannot be recommended at this time.

**Adverse Reactions**

The incidence of adverse effects has been ascertained from controlled clinical studies conducted in the United States and is based on data from 859 patients who received Wytensin for up to 3 years. There is some evidence that the side effects are dose-related.

The following table shows the incidence of adverse effects occurring in at least 5% of patients in a study comparing Wytensin to placebo, at a starting dose of 8 mg b.i.d.

| Adverse Effect | Placebo (%) n = 102 | Wytensin (%) n = 109 |
|---|---|---|
| Dry mouth | 7 | 28 |
| Drowsiness or sedation | 12 | 39 |
| Dizziness | 7 | 17 |
| Weakness | 7 | 10 |
| Headache | 6 | 5 |

In other controlled clinical trials at the starting dose of 16 mg/day in 476 patients, the incidence of dry mouth was slightly higher (38%) and that of dizziness was slightly lower (12%), but the incidence of the most frequent adverse effects was similar to the placebo-controlled trial. Although these side effects were not serious, they led to discontinuation of treatment about 15% of the time. In more recent studies using an initial dose of 8 mg/day in 274 patients, the incidence of drowsiness or sedation was lower, about 20%.

Other adverse effects were reported during clinical trials with Wytensin but are not clearly distinguishable from placebo effects and occurred with a frequency of 3% or less:

Cardiovascular—chest pain, edema, arrhythmias, palpitations.
Gastrointestinal—nausea, epigastric pain, diarrhea, vomiting, constipation, abdominal discomfort.
Central nervous system—anxiety, ataxia, depression, sleep disturbances.
ENT disorders—nasal congestion.
Eye disorders—blurring of vision.
Musculoskeletal—aches in extremities, muscle aches.
Respiratory—dyspnea.
Dermatologic—rash, pruritus.
Urogenital—urinary frequency, disturbances of sexual function.
Other—gynecomastia, taste disorders.

**Drug Abuse and Dependence**

No reported dependence or abuse has been associated with the administration of Wytensin.

**Overdosage**

Accidental ingestion of Wytensin caused hypotension, somnolence, lethargy, irritability, miosis, and bradycardia in two children aged one and three years. Gastric lavage and administration of pressor substances, fluids, and oral activated charcoal resulted in complete and uneventful recovery within 12 hours in both patients.

Since experience with accidental overdosage is limited, the suggested treatment is mainly supportive while the drug is being eliminated from the body and until the patient is no longer symptomatic. Vital signs and fluid balance should be carefully monitored. An adequate airway should be maintained and, if indicated, assisted respiration instituted. There are no data available on the dialyzability of Wytensin.

**Dosage and Administration**

Dosage with Wytensin should be individualized. A starting dose of 4 mg twice a day is recommended, whether Wytensin is used alone or with a thiazide diuretic. Dosage may be increased in increments of 4 to 8 mg per day every one to two weeks, depending on the patient's response. The maximum dose studied to date has been 32 mg twice daily, but doses as high as this are rarely needed.

**How Supplied**

Wytensin® (guanabenz acetate) Tablets, Wyeth®, are available in the following dosage strengths:

4 mg, NDC 0008-0073, white, round tablet marked "WYETH" and "73", in bottles of 100.

8 mg, NDC 0008-0074, white, round, scored tablet marked "WYETH" and "74", in bottles of 100.

**Keep bottles of Wytensin Tablets tightly closed.**
**Dispense in tight containers.**
**Protect from light.**

Issued August 17, 1982

# Radionuclide Analysis of Peak Filling Rate, Filling Fraction, And Time to Peak Filling Rate

## Response to Supine Bicycle Exercise in Normal Subjects And Patients With Coronary Disease

G. B. JOHN MANCINI, MD, FRCP(C), ROBERT A. SLUTSKY, MD, SHARON L. NORRIS, MD, VALMIK BHARGAVA, PhD, WILLIAM L. ASHBURN, MD, and CHARLES B. HIGGINS, MD

**Using gated equilibrium radionuclide angiography, variables of diastolic filling were analyzed at rest and during supine bicycle exercise in normal subjects (Group 1, n = 18), coronary patients with normal resting ejection fractions (Group 2, n = 26), and coronary patients with reduced resting ejection fractions (Group 3, n = 8). Indexes analyzed were peak filling rate and filling fraction during the first third of diastole. At rest, the peak filling rate was significantly lower in coronary patients than in normal subjects (3.18 ± 0.82 end-diastolic volume [EDV]/s in Group 1 versus 2.41 ± 0.66 EDV/s in Group 2, p <0.005; and 1.34 ± 0.26 EDV/s in Group 3, p <0.001 versus Group 1). These differences persisted at peak exercise. Coronary patients also had significantly lower filling fractions at rest and during exercise than did normal control subjects. The time from end-systole to peak filling rate was longer at rest in patients in Group 2 (203 ± 52 ms) than in subjects in Group 1 (172 ± 50 ms, p <0.025). This remained true when the time to peak filling was normalized by the R-R interval. Although the exercise time to peak filling was longer in coronary patients in both Groups 2 and 3 than in Group 1, these differences were not apparent when the interval was normalized by the R-R interval. Thus, abnormalities in peak filling rate and filling fraction exist in patients with coronary disease both at rest and during exercise, but large overlaps exist between normal and coronary patients. Caution is advised in comparing the timing of events during diastole because apparent group differences may be related in part to rest or exercise heart rate.**

Traditional analysis of left ventricular diastolic performance requires invasive pressure monitoring and cineangiographic techniques.[1,2] These approaches have occasionally uncovered abnormal diastolic performance in coronary patients that has not always been associated with impaired systolic performance. Abnormalities have occurred in patients studied at rest who have coronary disease even when acute ischemia or previous myocardial infarction was not found.[3,4] In addition, these disturbances can also be induced by acute ischemia[5–9] and other forms of stress.[10]

Noninvasive characterization of diastolic performance was recently performed with both gated equilibrium radionuclide ventriculography[11] and first-pass radionuclide ventriculography.[12] Others have evaluated diastolic radionuclide data at rest and during exercise[13] in normal and coronary patients and found abnormalities in left ventricular filling in patients with coronary disease. The purpose of this study was to reexamine a number of noninvasive variables of diastolic function at rest and during exercise in patients with coronary heart disease that have been suggested as being reliable and subtle markers of cardiac dysfunction.

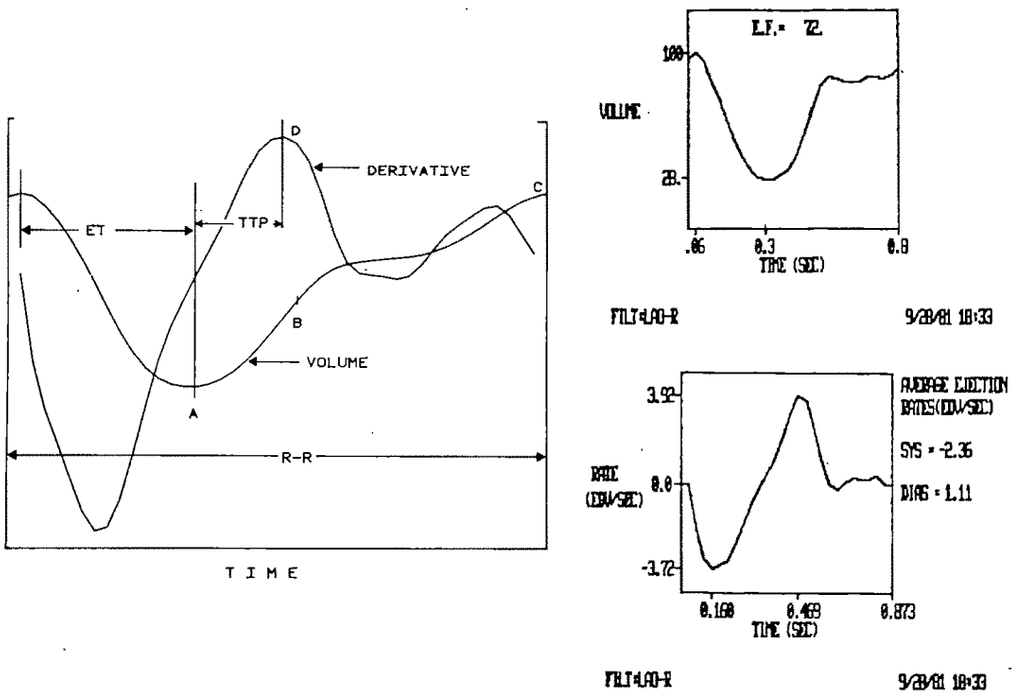

**FIGURE 1. Left,** volume curve and first derivative curve. Time is given along the abscissa. ET = ejection time; TTP = time to peak filling rate. The time interval between points A and B constitutes one third of diastole (one third of the time between points A and C). The difference between counts at A and B divided by the counts at B expressed as a percentage defines the filling fraction. The peak filling rate is taken from the derivative curve at point D and expressed as end-diastolic volumes/second. **Right,** A typical volume and first-derivative curve. The data are derived from the filtered images, but the curves are not themselves smoothed.

Using gated equilibrium radionuclide angiography at rest and with symptom-limited supine bicycle exercise in normal subjects and patients with coronary disease, we performed the following study to (1) determine the peak left ventricular filling rate and filling fraction during the first third of diastole, (2) determine the behavior of these indexes with exercise, and (3) investigate the timing of the peak left ventricular filling rate both in absolute terms and in relation to the R-R interval and ejection time.

This study confirms and extends recent studies[11–13] using radionuclide techniques to evaluate abnormalities of diastolic filling in coronary patients. However, we attempt to demonstrate the potential methodologic limitations of this technique which often arise from the effects of changes in heart rate and the timing of atrial systole. Furthermore, an appreciation of the drawbacks in the use of these variables in assessing individual patients is provided.

## Methods

**Patient population:** Group 1 consisted of 18 normal control volunteers (aged 43 ± 4 years), 13 male and 5 female, without symptoms or signs of systemic disease. No subject was taking medications and all had normal resting radionuclide left ventricular ejection fractions, electrocardiograms, and physical examinations.

Group 2 consisted of 26 patients with coronary disease (aged 48 ± 6 years) with normal radionuclide left ventricular ejection fractions at rest (≥45%). Ten of them had had previous myocardial infarction as evidenced by a history of chest pain, an elevated serum creatinine kinase level, and characteristic electrocardiographic changes at least 6 months previously. No patient had evidence of valvular heart disease. Eleven were taking beta-blocking medications at the time of the study.

Group 3 consisted of 8 patients with coronary disease (aged 47 ± 6 years) with a depressed radionuclide left ventricular ejection fraction at rest (<45%). Four had had myocardial infarction at least 6 months earlier. One patient had no clinical history of infarction but had Q waves in the lateral limb leads. Two patients were taking beta-blocking medications and 1 was on chronic digitalis glycoside therapy. No patient had evidence of valvular heart disease.

**Equilibrium radionuclide angiography:** All studies were performed with a portable scintillation camera (Picker Dyna-Mo), with the gamma detector placed in the 45° left anterior oblique position with a 10 to 15° caudal tilt. A general purpose collimator was used in all studies, and the photopeak of the camera was set at 140 keV with a 20% window.

For analysis of left ventricular function, the data were reformatted with the aid of an electrocardiographic gate, allowing the production of composite 32-frame cardiac cycles. The scan frames were frequency filtered, using both spatial (5 × 5 point) and temporal (7 point) filters. Cardiac cycles that fell outside a ±10% range of the R-R interval were excluded. Using threshold and second derivative techniques, a variable left ventricular region-of-interest was obtained for the 32 frames of the composite cardiac cycle. These regions were applied to the filtered data to produce ventricular volume curves. Background was assigned lateral to the left ventricle at end-systole.[14,15] All data were analyzed using a general nuclear medicine computer (MDS, A², Ann Arbor, Michigan).

The following variables were analyzed (Fig. 1). Left ventricular ejection time was defined as the time between the

early apex (end-diastole) of the time-activity (volume) curve and its nadir (end-systole). End-diastole was defined by the volume curve. The first derivative of the volume curve provides frame by frame ejection and filling rates. The early peak negative deflection of this first derivative curve was defined as peak ejection. The late positive peak was defined as peak filling rate (EDV/s). The time to peak filling rate was defined as the time from end-systole on the volume curve to the time of the late peak of the first derivative curve. The filling fraction was obtained by dividing the time from end-systole to the end of the R-R interval into 3 equal intervals; the time for the first third of diastole could then be determined. Filling fraction was then defined as the difference between the counts at the end of the first third of diastole and at end-systole divided by the counts at the end of the first third of diastole and expressed as a percentage.

At rest, the duration of all frames was ≤0.03 second (mean 0.024 ± 0.003), and with exercise all frame durations were ≤0.02 second (mean 0.013 ± 0.002).[16]

The "weighted forward backward breakup volume curve" used in this study has become a standard commercial algorithm used by many laboratories to evaluate cardiac function. Methods for merging the forward and backward derived curves and the importance of a number of weighting techniques were investigated in our laboratory by studying 5 dogs undergoing atrial pacing and repeated left ventriculography and by performing frame-by-frame analyses at several paced rates. Ejection fraction as well as peak ejection and filling rates were derived from either QRS-gated forward, reverse, or composite curves generated by both linear and exponential weighting of the forward and reverse breakup curves. These values were compared with results obtained from the mean heart rate-volume curves. Linear weighting interpolation for deriving the composite curve provided a reasonable approximation of the mean heart rate-volume curve. However, the correlation of filling rates and later diastolic volume curve events could more accurately be characterized by the forward-reverse breakup technique than by the forward curve alone.[17] In the present study, for analysis of forward breakup, the radionuclide volume curves were gated with respect to the onset of the QRS interval and averaged with a symmetrical weight distribution forward in time after the ±10% R-R interval exclusion. Beats were weighted in proportion to the mean heart rate beat, with the mean heart rate beats receiving the greatest weight. The reverse breakup curve was obtained by aligning the tail end of the curves (backward in time) with the same weights. The forward and reverse generated curves were then combined to generate the composite volume curve. The composite curves were produced by assuming that the initial portion of the forward curve and the terminal portion of the reverse curve were accurate and that the remaining intermediate portion of the curves could be obtained by linear weighting of the forward and reverse curves. The ejection fraction, filling fraction, peak filling rate, and time from

Values are mean ±1 standard deviation. FF = filling fraction; LV = left ventricular; PFR = peak filling rate.

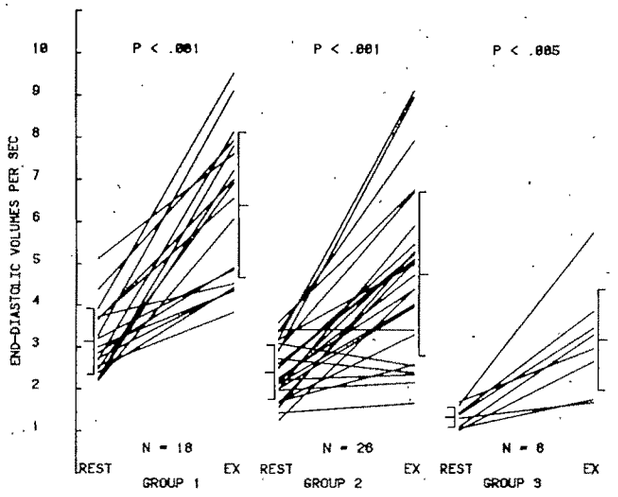

**FIGURE 2.** The response of peak diastolic filling rate to exercise (EX) in normal subjects (Group 1) and patients with coronary disease with normal (Group 2) and decreased rest left ventricular ejection fraction (Group 3). P values refer to comparisons of rest and exercise values within each group. Mean values ±1 standard deviation are shown by the **bars.**

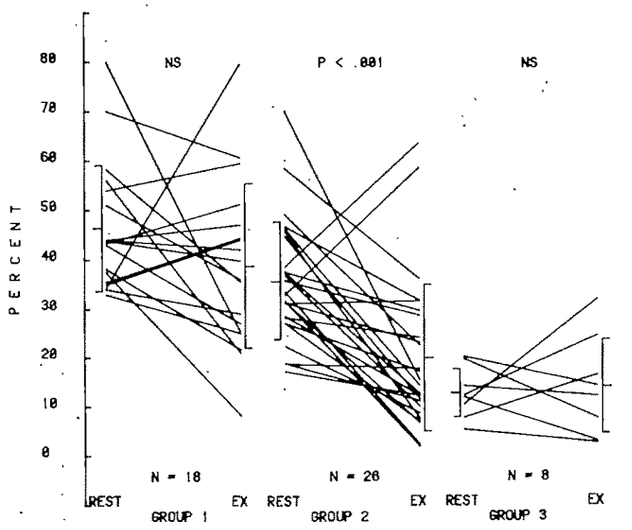

**FIGURE 3.** The response of the filling fraction to exercise (EX) in normal subjects (Group 1) and patients with coronary artery disease with normal (Group 2) and decreased rest ejection fraction (Group 3). P values refer to comparisons of rest and exercise values within each group. Mean values ±1 standard deviation are shown by the **bars.** NS = not significant.

end-systole to peak filling rate were determined from the merged, composite (that is, interpolated) volume-time curve.

In a subgroup of 26 patients, variability in the measurement of the indexes of interest between 2 observers was as follows: peak filling rate, ±8% (range −0.06 to +0.46 EDV/s); filling fraction, ±9% (range −8 to +8 filling fraction percentage units); and time from end-systole to peak filling rate, ±4% (range −20 to +10 ms).

**Clinical protocol:** The patients' own red cells were labelled ex vivo with 20 to 25 mCi of technetium-99m using the method of Smith and Richards.[18] The details of the exercise protocol were previously reported.[19,20] After equilibrium was reached, electrocardiographically gated scintillation data were collected for 5 minutes at rest. Graded supine exercise was performed and additional data collections were made at maximal exercise (usually 3 minutes in duration). Exercise was discontinued if the patient complained of shortness of breath, fatigue, or chest discomfort but was not limited by S-T segment depression. None of the normal subjects complained of chest pain or developed S-T segment depression. In the coronary patients with a normal left ventricular ejection fraction at rest, 14 of the 26 had an abnormal S-T segment response to exercise (≥1 mm S-T depression in 1 or more of lateral chest leads $V_3$ to $V_6$). Ten of them also had chest pain and in 2 of them the S-T response consisted of S-T elevations at peak exercise. In the coronary patients with a low left ventricular ejection fraction, 3 of the 8 had chest pain at peak exercise, in 2 of whom S-T segment depressions developed ≥1 mm, whereas 1 had S-T elevation.

All patients gave informed consent to this protocol which was approved by the University of California, San Diego Human Subjects Committee.

**Statistics:** Data are given as the group mean ±1 standard deviation. Comparisons were performed by the appropriate paired or unpaired Student's *t* test. Correlations were tested by linear regression analysis.

## Results

**Ejection fraction and diastolic filling indexes at rest and during exercise (Table I, Fig. 2 and 3):** Table I summarizes the results of ejection fraction, peak filling rate, and filling fraction in the 3 groups. The ejection fraction increased significantly with exercise in the normal subjects did not change in either group of coronary patients.

At rest, the peak filling rate was highest in the normal group (Group 1) and lowest in coronary patients with a depressed resting ejection fraction (Group 3) (3.13 ± 0.82 versus 1.34 ± 0.26 EDV/s, $p < 0.001$). In addition, coronary patients with a normal resting ejection fraction had lower peak filling rates at rest than did normal subjects ($p < 0.005$). With exercise, all 3 groups showed significant increases in peak filling rates (Fig. 2), but once again coronary patients had significantly lower values compared with the normal group. Coronary patients in Group 3 who had the lowest exercise ejection fractions also attained the lowest exercise peak filling rates. The magnitude of changes was greatest in Group 1 (+3.26 ± 1.70 EDV/s) compared with Group 2 (+2.36 ± 1.75 EDV/s, $p < 0.05$ versus Group 1) and Group 3 (+1.86 ± 1.10 EDV/s, $p < 0.001$ versus Group 1).

The filling fraction showed a similar trend at rest, that is, normal subjects had the highest filling fractions and coronary patients with low resting ejection fractions had the lowest filling fractions. Group 2 patients with normal resting ejection fraction had filling fractions of intermediate magnitude between Group 1 and Group 3. In contrast to peak filling rate, the filling fraction showed no significant change with exercise in the normal subjects or in coronary patients with subnormal ejection fractions at rest (Group 3). Furthermore, Group 2 patients showed a significant decrease in filling fraction with exercise (Fig. 3). The exercise filling fraction was lower in both groups of coronary patients than in normal subjects.

Values are mean ±1 standard deviation. EF = ejection fraction; ET = ejection time; TTP = time from end-systole to peak filling rate.

**Analysis of timing variables (Table II, Fig. 4 and 5):** Table II summarizes the results of timing variables at rest and with exercise in all 3 groups. The R-R interval and ejection time were not different at rest among the groups, and in all 3 groups these intervals shortened significantly with exercise. During exercise the R-R interval was shortest in normal subjects, longest in Group 3 patients, and intermediate in Group 2 patients. The exercise ejection time was similar in Group 1 and 2 but was longer in Group 3 (214 ± 42 ms versus 164 ± 31 ms in normal subjects, $p < 0.005$).

Group 2 patients had a longer rest time to peak filling rate (203 ± 51 ms) than did normal subjects (172 ± 50 ms, $p < 0.025$), and this difference persisted when it was expressed as a function of the R-R interval but not when expressed as a function of the ejection time. However, Group 3 patients had a resting time to peak filling rate that was similar to that of the normal group, and normalization by R-R interval or ejection time did not help distinguish them from normal subjects.

With exercise the time to peak filling rate decreased significantly in Groups 1 and 2, but this change was not apparent when the interval was expressed as a function of the ejection time. The exercise time to peak filling rate tended to account for a greater proportion of the R-R interval in all 3 groups and statistical significance was achieved in Groups 1 and 2 (19 ± 4% at rest versus 26 ± 9% with exercise, $p < 0.05$ for Group 1; 24 ± 7% at

Values are mean ±1 standard deviation. ECG = electrocardiographic.

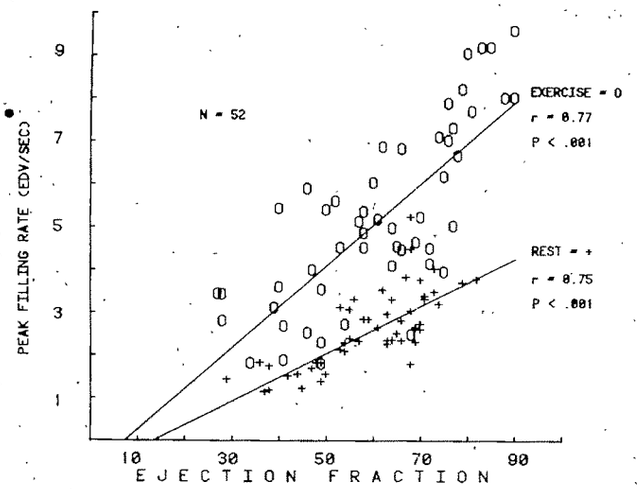

**FIGURE 6.** Correlation of ejection fraction and peak filling rate at rest and exercise for the entire study population.

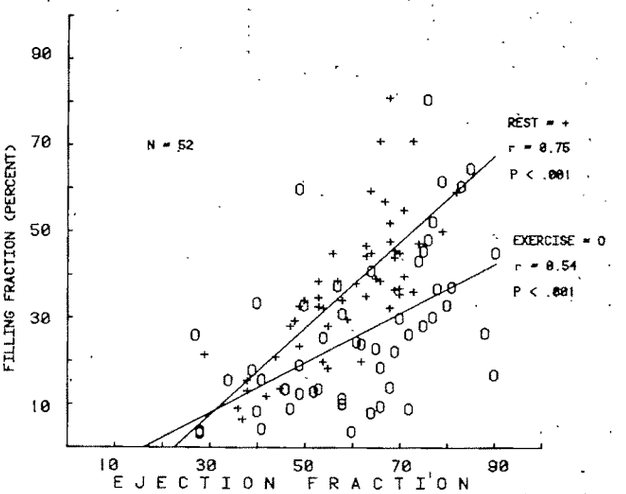

**FIGURE 7.** Correlation of ejection fraction and filling fraction at rest and exercise for the entire study population.

rest versus 28 ± 10% with exercise, $p < 0.05$ for Group 2).

The time to peak filling rate was longer with exercise in both coronary groups when compared with normal subjects, but this difference was lost when normalization by R-R interval and ejection time was undertaken.

**Subclassification of coronary patients with normal rest left ventricular ejection fraction (Group 2):** To further define the timing of diastolic events and the factors that might affect them, patients in Group 2 were analyzed with respect to intake of beta-blocking medication (n = 11), presence of previous myocardial infarction (n = 10), occurrence of an ischemic electrocardiographic response to exercise (n = 14), and occurrence of an abnormal ejection fraction response to exercise (n = 17). The ejection fraction response to exercise was considered abnormal when the exercise ejection fraction was <55% or failed to increase by 5% from a normal resting value.

The rest and exercise filling indexes and timing variables are summarized in Tables III and IV, respectively. Results in normal subjects are provided for ease of comparison. In general, the subgroups behaved as did the entire group with few exceptions. Of importance was that (1) coronary patients with a normal ejection fraction response to exercise attained a mean peak filling rate that was not statistically different from the values of the normal subjects, and (2) patients ingesting beta-blocking drugs had a longer resting time to peak filling rate than did normal subjects even when this interval was normalized by the R-R interval.

**Relation of filling rates to ejection fraction:** The rest and exercise peak filling rates are shown as a function of the corresponding rest and exercise ejection fraction for all patients in Figure 6. There was a significant correlation between these 2 variables both at rest ($r = 0.75$, $p < 0.001$) and at peak exercise ($r = 0.77$, $p < 0.001$). For the population as a whole, the filling fraction and ejection fraction showed a significant correlation at rest ($r = 0.75$, $p < 0.001$), and this correlation, although significant, was only fair at peak exercise ($r = 0.54$, $p < 0.001$) (Fig. 7).

**Sensitivity and specificity of diastolic variables in detecting coronary artery disease:** From our normal population we defined normal diastolic indexes in 2 ways, by using (1) 2 standard deviations from the group mean, or (2) the most extreme normal value as our cutoff criterion. The sensitivities (the number of true-positive tests divided by the number of patients with coronary artery disease) for detecting coronary disease in patients with a normal resting ejection fraction (Group 2, n = 26) are shown in Table V. Using these criteria, the specificity (number of true-negative tests

**TABLE V Sensitivity of Diastolic Variables for the Detection of Coronary Artery Disease in Patients With Normal Rest Left Ventricular Ejection Fraction (Group 2, n = 26)**

* Defined by using ±2 standard deviations from mean value of normal group. † Defined by using the extreme value from the normal group. E = exercise; FF = filling fraction; PFR = peak filling rate; R = rest; TTP = time to peak filling rate; TTP/R-R = time to peak filling rate normalized by the R-R interval. Numbers in parentheses indicate number of patients.

divided by the number of subjects without coronary disease) and predictive accuracy (the number of true-positive tests divided by the total number of positive tests) were each 100%.

## Discussion

Traditional analysis of isovolumic relaxation and diastolic behavior requires invasive angiocardiographic techniques to relate changes in pressure to changes in volume. This interrelation is governed not only by properties intrinsic to the ventricular muscle, such as elastic and viscous properties, but also by extrinsic factors which include the pericardium, atrial systole, heart rate, arterial pressure, and ventricular interaction.[2,21–24] Also, the pressure-volume relation in diastole is curvilinear such that the ventricle is relatively compliant at low volumes but becomes progressively less so as volumes increase.

Patients with coronary disease may manifest both acute and chronic alterations in the diastolic pressure-volume relation. In some patients, diastolic pressure is elevated despite normal left ventricular volumes[3,25] and this elevation may be due to increased wall stiffness because of fibrosis. Transient changes in the diastolic pressure-volume relation can be induced by acute ischemia.[5,6,8–10] Mechanisms that may explain these changes are numerous and include incomplete or impaired relaxation, altered diastolic "tone," tension prolongation during recovery from hypoxia, and perhaps also ischemic contracture of myofibrils.[24] Others have demonstrated changes in viscous properties induced by ischemia.[21]

Radionuclide angiography provides merely a gross approximation of diastolic function because only relative volumes are determined and expressed as a function of end-diastolic counts. These volumes cannot be related to intraventricular pressure without resorting to invasive techniques. In addition, it is well known that mere changes in ventricular volume without ischemia can increase chamber stiffness without implying a change in muscle stiffness.[1] Furthermore, the mechanisms involved in abnormalities of timing of events during various phases of the cardiac cycle cannot specifically be delineated without knowing the timing of valvular opening and closing. This knowledge cannot be provided by analysis of a radionuclide time-activity curve alone. Hence, it should be appreciated that the time from end-systole to peak filling rate contains both isovolumic relaxation as well as early diastolic filling. Anomalies in this interval may be difficult to interpret not only because of the combination of these 2 distinct phases of the cardiac cycle, but also because changes in diastolic filling may be affected by aberrations in myocardial relaxation.[2,24,26,27] Nevertheless, these methods provide an attractive qualitative approach to an analysis of diastolic function which circumvents the invasive angiocardiographic techniques and can readily be applied to large patient populations.

Relatively little data presently exist on the radionuclide assessment of diastolic function at rest and with exercise. Our determination of peak left ventricular filling rates using gated equilibrium radionuclide angiography at rest is in close agreement with those of Bonow et al[11] and Reduto et al,[13] the latter group having used first-pass techniques during upright exercise as well. In addition, the values are comparable to those calculated by Hammermeister and Warbasse,[4] using angiographic techniques. In contrast, Kemper et al[12] report markedly lower values at rest, the reason for which is not readily apparent from their report.

Clear differences in the peak filling rate were present at rest, the normal group having the highest values and the coronary group with low resting ejection fractions having the lowest values. This finding agrees with those of other investigators.[11,13] However, despite this general trend, substantial overlap exists between normal and coronary patients except when left ventricular dysfunction is already profound and readily apparent (Fig. 2). Thus, the usefulness of this isolated measurement at rest as a marker of coronary disease in any individual patient is limited (Table V). Only 11 of the 26 (42%) coronary patients with a normal ejection fraction at rest had a peak filling rate lower than the lowest control value. In contrast, 76% of the coronary patients with a normal resting ejection fraction reported on by Bonow et al[11] had a low peak filling rate. One reason for this difference may be the number of patients examined, our groups being smaller. However, the problem of overlap in these groups is still apparent.

The peak filling rate at rest in the coronary patients was lower than that in the normal subjects even when systolic function at rest was normal. The explanation for this observation in coronary patients without evidence of infarction or acute ischemia is not readily apparent. As suggested,[11] it may be due to (1) clinically inapparent ischemia, too mild to cause angina, electrocardiographic changes, or abnormalities of systolic function, (2) previous periods of ischemia which may produce subtle, irreversible changes in left ventricular relaxation without altering systolic function, or (3) previous periods of ischemia which may produce very slowly reversible changes in diastolic filling that are more long-lived than changes in systolic performance. Little direct evidence for these hypotheses is presently available. When global ejection fraction is taken as the measure of systolic function, peak filling rate appears to be more sensitive to the presence of coronary disease (that is, 42% of coronary patients with a normal rest ejection fraction had a low peak filling rate). However, when a systolic variable employing differentiation is assessed, such as peak ejection rate, it has also been abnormal in coronary patients at rest without infarction, acute ischemia, or abnormal ejection fraction when compared with that of normal individuals.[16,28] This observation agrees with the work of Hammermeister and Warbasse[4] who also noted that in the absence of valvular disease, peak rate of volume change was similar in both systole and diastole and both were lower in coronary patients when compared with normal subjects. Therefore, comparison of the sensitivity of ejection fraction and peak diastolic filling rate as a marker of coronary disease may in some respects be inappropriate. It should also be readily apparent that such abnormalities are not likely to be specific for the detection of

coronary disease, because patients with constrictive pericarditis, some forms of cardiomyopathy, and even mitral stenosis may manifest abnormalities of diastolic filling at rest.

The response of peak filling rate to exercise is shown in Figure 2. The rates increased significantly from the value at rest in all 3 groups; however, both the increases and the absolute rates attained were lower in coronary patients. This behavior was also noted by Reduto et al.[13] There was no discernible effect on this behavior with respect to the presence or absence of propranolol, previous myocardial infarction, or a positive electrocardiographic response to exercise. However, patients with a normal ejection fraction response to exercise attained peak filling rates that were similar to those in normal patients.

It is important to emphasize that a fundamental difference exists between rest and exercise in what is measured as peak filling rate. Although at rest the contribution of atrial systole is usually apparent and can readily be excluded, the same is not true for exercise when the contribution of atrial systole may be a major determinant of the measured peak filling rates because of the much shorter R-R interval. This limitation of the methodology is not easily circumvented. Nevertheless, all patients remained in sinus rhythm during exercise, and the behavior of peak filling rates with exercise still provides information about differences in the way volume is handled in the different groups, despite the complicating feature of atrial systole.

The filling fraction as measured during the first third of diastole was proposed by Reduto et al[13] as an index of diastolic function. They found that, on the whole, coronary patients had a lower filling fraction at rest and during exercise when compared with that of normal subjects. However, despite this, they found that substantial overlap existed between these groups. Filling fraction did not change significantly from rest to exercise in their normal subjects and in the coronary patients with a normal ejection fraction response to exercise. In contrast, their patients with an abnormal ejection fraction response showed a decrease in filling fraction with exercise. Our data agree with this both in magnitude and in the directional changes (Table I, Fig. 3). However, when considering our coronary patients with a normal resting ejection fraction, we found that virtually all subgroups had a decreased filling fraction during exercise, including patients with a normal ejection fraction response to exercise and absent electrocardiographic responses (Table III). This finding suggests that the response of the filling fraction to exercise may provide useful clinical information in the detection of coronary disease when other methods have failed. However, it should be emphasized that this decrease in filling fraction occurred very frequently in normal subjects (Fig. 3). This behavior in normal patients was also noted by Reduto et al,[13] who thought it might represent a normal physiologic response due to incomplete left ventricular relaxation associated with rapid heart rates. This finding has been documented in dogs undergoing atrial pacing by Weisfeldt et al[26] and Mitchell et al.[27] Alternatively, untrained normal subjects have increased ventricular volumes with exercise,[29] which may result in an increased chamber stiffness in the absence of ischemia.

Measurement of the filling fraction during the first third of diastole has the advantage over the peak filling rate of potentially excluding the effect of atrial systole during exercise at rapid heart rates. However, because the filling fraction is arbitrarily measured during the first third of diastole, it is difficult to reckon with the meaning of changes in this variable. With exercise, diastole in total is shortening, with most of the shortening occurring during slow filling, as is isovolumic relaxation. The period encompassed by the filling fraction measurement may therefore be very different from rest to exercise, that is, at rest the filling fraction might extend into slow filling, whereas during exercise it might end sometime during rapid filling.

Further characterization of diastolic behavior is provided by an analysis of the time of occurrence of peak filling rate. At rest the time from end-systole to the occurrence of peak filling is longer in coronary patients than in normal subjects[11,12,16] and this is true even in many patients without evidence of previous infarction or acute ischemia. Bonow et al[11] showed that this interval by itself did not appear to be useful as a predictor of coronary disease, but when combined with subnormal peak filling rate at rest, the sensitivity for detection of coronary disease was increased from 85 to 91%. Kemper et al[12] also found that this isolated interval was not a useful predictor of coronary disease. Neither of these groups corrected this interval for the duration of the R-R interval. Although the normal and coronary patients reported on by Bonow et al[11] had a similar resting heart rate, in the usual clinical situation in which an individual's timing interval is to be evaluated, a meaningful interpretation can only be provided if the effects of heart rate can be excluded, especially because many patients undergo diagnostic tests while ingesting beta-blocking medications. It appears to us that normalization of the interval by the R-R interval is a reasonable approach to this problem. As in other studies,[11,12] we found that the time to peak filling was longer in coronary patients with a normal ejection fraction than in our control subjects, and this relation held true when it was normalized by the R-R interval. Furthermore, patients ingesting propranolol had an abnormal interval even when normalized by R-R interval. At rest, however, this normalized interval identified only 23% of coronary patients with a normal resting ejection fraction (Table V).

With exercise, the time to peak filling appeared longer in coronary patients with a normal resting ejection fraction than in the control group ($p < 0.025$); however, those differences disappeared when the interval was normalized by the R-R interval. That is to say, although our normal patients had the shortest time to peak filling, they also had the shortest R-R interval with exercise. The coronary patients had both a longer time to peak filling and a longer R-R interval. Thus, when the interval is expressed as a percentage of the R-R interval,

the apparent differences between groups is minimized. Therefore, although real differences evidently exist in the timing of diastolic events, caution is advised in the interpretation of this interval in an individual patient if the effects of the underlying heart rate are not first taken into account.

# Determinants of Variable Exercise Performance Among Patients With Severe Left Ventricular Dysfunction

MICHAEL B. HIGGINBOTHAM, MB, KENNETH G. MORRIS, MD, ERIC H. CONN, MD, R. EDWARD COLEMAN, MD, and FREDERICK R. COBB, MD

**The relation between bicycle exercise performance and determinants of central and peripheral cardiovascular function was assessed in 17 patients with class II to III heart failure and in 9 normal subjects. Proportional changes in oxygen consumption ($VO_2$) from rest (R) to maximal exercise (Ex), or Mets, were used as an objective measure of the exercise capacity or functional reserve of the cardiovascular system. Left ventricular ejection fraction (EF) and proportional changes in end-diastolic volume, stroke volume, and cardiac output were determined from appropriate count data by equilibrium radionuclide angiography. Proportional changes in arteriovenous oxygen difference ($A\text{-}VO_2$) were derived from the equation $Ex/_R\ A\text{-}VO_2 = Ex/_R\ VO_2 \div Ex/_R\ CO$, where CO = count output.**

**Each subject exercised to an anaerobic end-point. Maximal $VO_2$ was significantly lower in patients than in normal subjects. Because $Ex/_R\ A\text{-}VO_2$ was comparable in normal subjects and patients, the lower exercise performance in patients resulted from a reduced count output response. The reduced CO response in patients resulted from failure of the ejection fraction to increase or from an attenuated heart rate response, or both.**

**Exercise performance was variable in both groups. Multivariable analysis in the patient group identified changes in heart rate, count output, and $A\text{-}VO_2$ with exercise as important predictors of Mets, but found no relation between Mets and changes in ejection fraction or stroke counts during exercise. Similarly, multiple regression analyses between Mets and determinants of cardiovascular function demonstrated significant correlations with $Ex/_R$ heart rate, $Ex/_R$ count output, and $Ex/_R\ A\text{-}VO_2$ in both groups. In patients, EF at rest ranged from 0.09 to 0.36, but it did not correlate with Mets, nor did changes in ejection fraction, stroke counts, or end-diastolic counts during exercise. The variable exercise performance among patients with severe left ventricular dysfunction was determined predominantly by a variable heart rate and $A\text{-}VO_2$ response and not by rest or exercise indexes of left ventricular function.**

Patients with ventricular dysfunction demonstrate a generally reduced but highly variable exercise capacity. Despite severe ventricular dysfunction, certain patients may even have normal exercise tolerance.[1] The parameters that determine this variable ability to exercise have not been delineated. Recent studies[1–4] show that measurements of left ventricular function at rest have little or no correlation with exercise capacity in patients with heart failure. No previous study has related central and peripheral components of cardiovascular function during exercise with objective measurements of exercise capacity in patients with a wide range of ventricular dysfunction.

The purpose of the present study was to relate indexes of left ventricular and peripheral cardiovascular function at rest and during exercise with maximal exercise capacity during upright bicycle ergometry. Left ventricular function was measured noninvasively with radionuclide angiography, and maximal exercise capacity was assessed by determining maximal oxygen consumption and achievement of anaerobic end-points of exercise.

## Methods

**Study groups:** The study was performed in 17 patients aged 27 to 68 years with New York Heart Association functional class II to III heart failure and in 9 subjects aged 31 to 55 years without cardiovascular disease. Clinical characteristics are summarized in Table I. All patients were male. Twelve patients had coronary artery disease with documented previous myocardial infarction. Four patients had idiopathic dilated cardiomyopathy. One patient had heart failure after successful aortic and mitral valve replacement and no clinically apparent valvular insufficiency. In all cases, cardiac failure had been clinically stable for at least 2 months. All patients were receiving digoxin and diuretics at the time of the study; none was receiving beta-adrenergic blocking drugs or vasodilator drugs other than occasional sublingual nitroglycerin. Patients were excluded from the study if they had angina pectoris that limited exercise, physical or radiographic

signs of obstructive lung disease, or intermittent claudication.

The control group consisted of 6 normal volunteers who had no symptoms or signs of cardiovascular disease, 1 subject who had no signs or symptoms of cardiovascular disease but was referred for evaluation of exercise intolerance, and 2 subjects referred for evaluation of chest pain who had normal cardiac catheterization findings. Written informed consent was obtained from each subject.

**Exercise test protocol:** The exercise test was performed in the postabsorptive state. Administration of digoxin and diuretics was continued. Exercise was performed in the upright position with the subject sitting on an isokinetic bicycle ergometer (Fitron). The electrocardiogram was monitored continuously. The standard limb leads and leads $V_5$ and $V_6$ were recorded initially and after each minute of exercise. Arterial blood pressure was measured by cuff manometry at rest and during each minute of exercise. Exercise began at 150 kpm/min (50 W); the work load was increased by 150 kpm every 3 minutes. The exercise rate was constant at 60 rpm. Exercise was continued until limited by excessive fatigue or shortness of breath, or both.

**Respiratory gas analysis and calculation of anaerobic threshold:** The concentration of expired oxygen was analyzed continuously with a Beckman OM-14 oxygen analyzer; carbon dioxide was analyzed with a Beckman LB-2 analyzer. Minute ventilation was measured with a Pneumoscan spirometer. Instruments were calibrated at the beginning of each study and before every measurement. Oxygen consumption ($\dot{V}O_2$) and carbon dioxide production ($\dot{V}CO_2$) were measured before exercise and during the third minute of each exercise stage. Appropriate corrections were made for barometric pressure and temperature of the expired gases. Maximal $\dot{V}O_2$ was calculated for each subject, and for descriptive purposes was expressed as a multiple of resting oxygen consumption, defined as Mets. Anaerobic end-points of exercise were confirmed from the ratio of $\dot{V}CO_2/\dot{V}O_2$ and from the ratio of minute ventilation/$\dot{V}O_2$ using criteria described by Wasserman and co-workers.[5,6]

**Radionuclide angiography:** Multigated radionuclide angiograms were recorded by labelling red blood cells in vivo with 30 mCi of technetium-99m. Radionuclide angiograms were acquired using a Searle L.E.M. mobile scintillation camera with a high sensitivity collimator and hardware zoom, and an R-wave triggered gate interfaced to a Medical Data Systems $A^2$ computer. Studies were acquired in the histogram mode, in a 64 × 64 matrix of 24 frames each containing 125,000 counts. The acquisition time was approximately 1.5 to 2 minutes for each study. Serial radionuclide angiograms were recorded before exercise and during the second and third minutes of each exercise stage.

The multigated radionuclide studies were analyzed without data processing. The left ventricular ejection fraction was calculated using a varying region of interest technique. Regions were assigned using an operator-assisted semiautomated edge-detection program. Analysis of counts in each region allowed the construction of time activity curves and the determination of ejection fraction. End-diastole (ED) and end-systole (ES) were determined from the peaks and troughs of the time activity curve, respectively. The ejection fraction (EF) was calculated from the following formula: EF = (ED counts-background) − (ES counts-background)/(ED counts-background). Relative stroke count (SC) changes from rest to exercise were derived from the background and time-corrected end-diastolic count rate (EDCR), thus: $Ex/_R$ SC = $Ex/_R$ EDCR × $Ex/_R$ EF. The end-diastolic count rate was in each case back-corrected to the time of the resting study to allow for isotope decay. The formula used was EDCRo = EDCRt × $e^{\lambda t}$, where EDCRo = the back-corrected value, EDCRt = the value recorded at time t, and $\lambda = 0.693$/isotope half-life. Relative count output changes as indexes of cardiac output changes from rest to exercise were calculated from the following formula: $Ex/_R$ CO = $Ex/_R$ SC × $Ex/_R$ HR, where HR = heart rate in beats/min.

Arteriovenous oxygen difference, or the difference between arterial and mixed venous oxygen content, was not measured directly in the study group. Relative changes in arteriovenous oxygen difference (A-$VO_2$) were derived from the equation $\dot{V}O_2$ = CO × A-$VO_2$, so that: $Ex/_R$ A-$VO_2$ = $Ex/_R$ $\dot{V}O_2$ × $R/_{Ex}$ CO. In the following sections the change in A-$VO_2$ will refer to this derived value.

The foregoing methods were validated in a group of 6 patients, 4 of whom were involved in the present study, who performed staged exercise in a manner identical to that described herein. The resting ejection fraction in this group ranged from 0.10 to 0.42 (mean 0.26). Arteriovenous oxygen difference was measured directly by sampling from a cannula in the brachial artery and a Swan-Ganz catheter in the pulmonary artery. Measurements were made at the beginning of the third minute of each exercise stage and thus coincident with the oxygen consumption and radionuclide measurements. Cardiac output was calculated at rest and during each exercise stage by the Fick method. Stroke volume was obtained by dividing cardiac output by heart rate.

Noninvasive and invasive measurements were compared by regression analysis and by comparing individual data as a function of progressive work load.

**Statistical analysis:** Group data of patients and normal subjects were compared using Student's *t* test. The relative importance of several cardiovascular variables as determinants of exercise capacity was assessed in the 17 patients by stepwise multivariable analysis. In addition, exercise performance as expressed by Mets was related to cardiovascular variables by multiple regression analyses. All group data were expressed as mean ± standard deviation.

## Results

**Validation studies:** Data in Figures 1 and 2 demonstrate the validity of the noninvasive measurements made in the present study. Proportional changes in stroke counts, count outputs, and derived A-$VO_2$ correspond well with direct measurements of stroke volume ($r = 0.67$), cardiac output ($r = 0.89$), and arteriovenous oxygen difference ($r = 0.78$) (Fig. 1). Figure 2 illustrates individual and mean data describing proportional changes in cardiovascular variables derived by noninvasive and direct measurements during progressive exercise; mean data were essentially the same.

Duplicate resting radionuclide studies were recorded in 11 of the 17 study patients. The mean ejection fraction of the group was 0.22 ± 0.06; the mean difference between the 2 ejection fraction measurements was 0.05

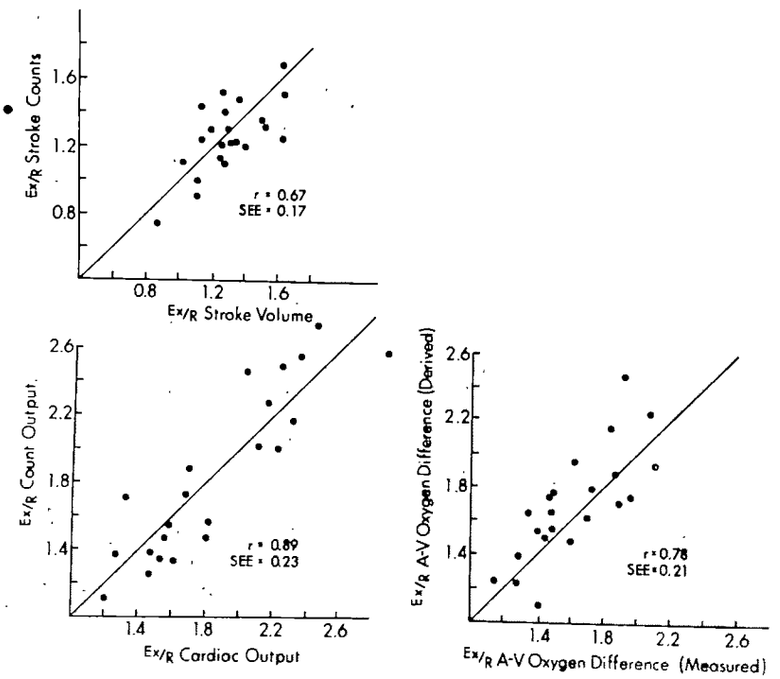

**FIGURE 1.** Validation of methods. The relation is shown between proportional ($Ex/_R$) changes in stroke volume, cardiac output, and arteriovenous oxygen differences (**horizontal axis**) and corresponding noninvasive estimates (**vertical axis**). The values represent data from various exercise stages in 6 patients. The line of identity is shown. SEE = standard error of the estimate.

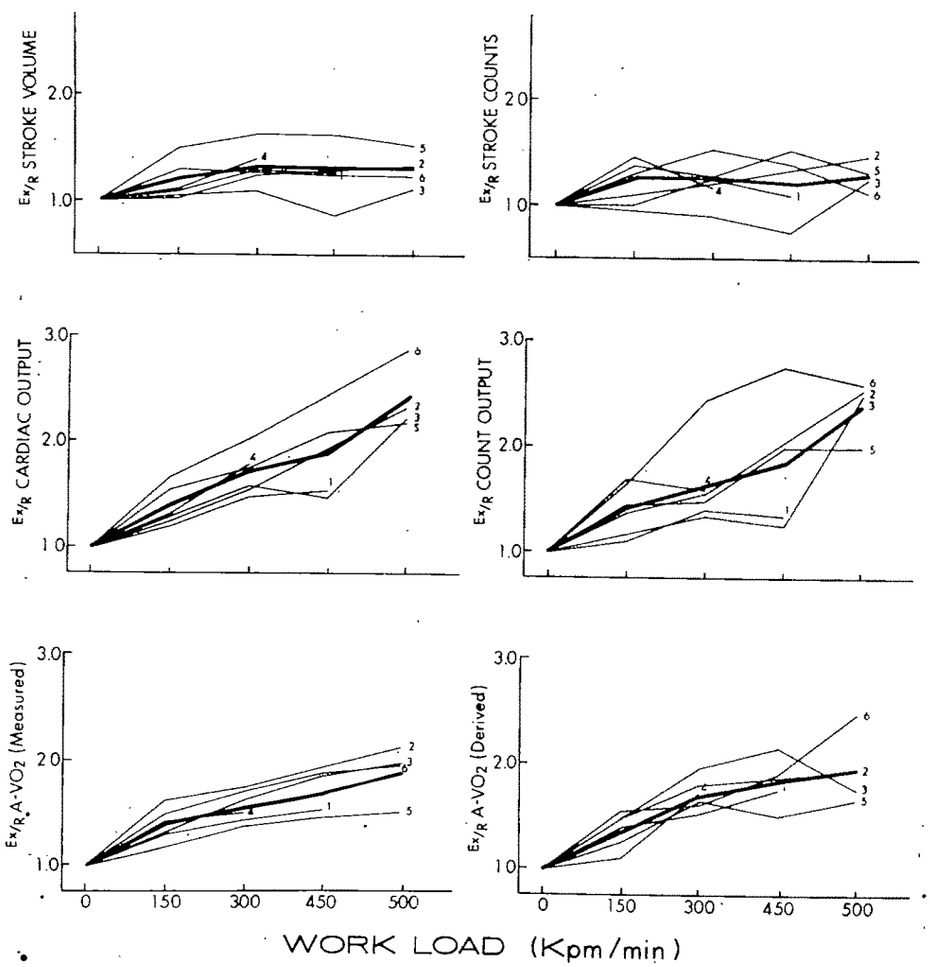

**FIGURE 2.** Validation of methods. Comparison between proportional ($Ex/_R$) changes in stroke volume, cardiac output, and arteriovenous oxygen differences (**left panels**) and the corresponding noninvasive estimates (**right panels**). Individual data from 6 patients are expressed as a function of work load. Mean data (**heavy lines**) are almost identical for invasive and noninvasive measurements.

**TABLE II Gas Exchange and Cardiovascular Performance in 9 Normal Subjects and 17 Patients With Cardiac Failure**

| | Rest | | | Maximal Exercise | | |
|---|---|---|---|---|---|---|
| | Normal Subjects | Patients | p | Normal Subjects | Patients | p |
| Work load | ... | ... | ... | 761 ± 170 | 476 ± 140 | <0.001 |
| $\dot{V}O_2$ | 4.5 ± 1.3 | 4.0 ± 1.1 | NS | 23.5 ± 7.6 | 14.8 ± 4.3 | <0.01 |

Values are mean ± standard deviation. NS = not significant; RQ = respiratory quotient; SBP = systolic blood pressure.

± 0.001. The mean difference in end-diastolic counts was 4.7 ± 2.7%.

**Left ventricular function at rest:** In patients there was a wide range of left ventricular dysfunction; the ejection fraction range was 0.09 to 0.36 (mean 0.23). The ejection fraction was at least 0.50 in all normal subjects (range 0.50 to 0.68; mean 0.60) (Table II).

**Exercise performance:** Exercise performance as expressed by maximal work load, $\dot{V}O_2$, or Mets was significantly reduced in patients compared with normal subjects (Table II). Among the 9 normal subjects, the 2 lowest values for Mets, 2.8 and 3.5, were seen in the patients investigated for chest pain. Neither took regular physical exercise. The highest value, 8.3, was seen in a subject who engaged in long-distance cycling. The relation between oxygen consumption ($\dot{V}O_2$) and work load is shown in Figure 3. Although at comparable work loads $\dot{V}O_2$ was similar in the patients and normal subjects, maximal $\dot{V}O_2$ was reduced greatly in the patients.

Each subject exercised in excess of the anaerobic end-point (Fig. 4). The respiratory quotient ($\dot{V}CO_2/\dot{V}O_2$) exceeded 1.0 in each subject at maximal exercise. The ventilatory equivalent (minute ventilation/$\dot{V}O_2$) initially decreased, then increased slowly before abruptly rising at the maximal work load in each subject. The respiratory quotients and ventilatory equivalents at maximal exercise were comparable in

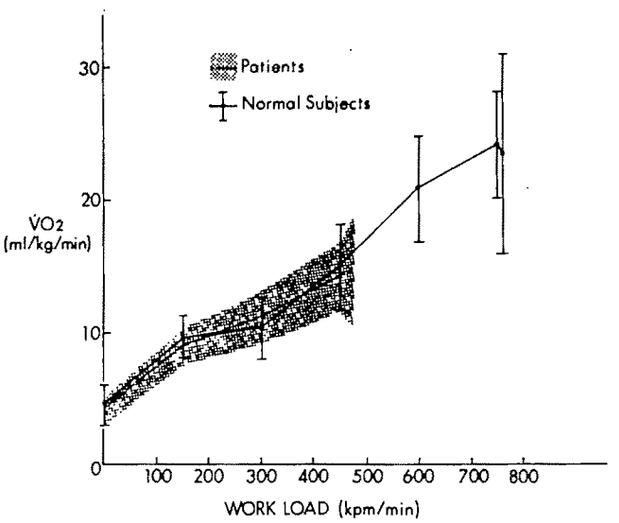

**FIGURE 3.** Relation between oxygen consumption ($\dot{V}O_2$) and work load with upright bicycle exercise in 9 normal subjects and 17 patients with left ventricular failure. Values represented are mean ± standard deviation.

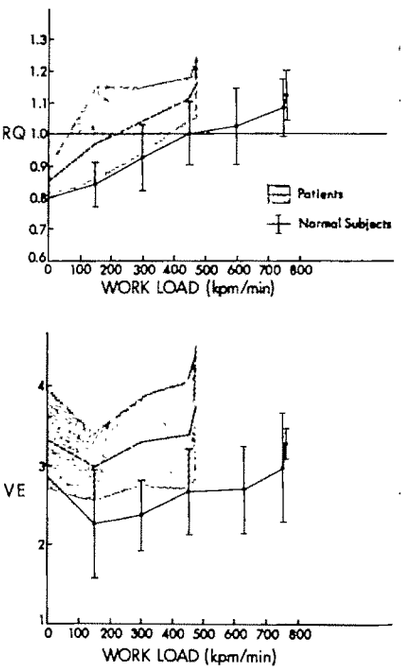

**FIGURE 4.** Changes in respiratory quotient (RQ) and ventilatory equivalent (VE) with progressive increases in work load during bicycle exercise in 9 normal subjects and 17 patients with left ventricular failure. Respiratory quotient represents the ratio of carbon dioxide production to oxygen consumption. Ventilatory equivalent expresses the ratio of minute ventilation to oxygen consumption. Comparable anaerobic end-points of exercise are seen in each group.

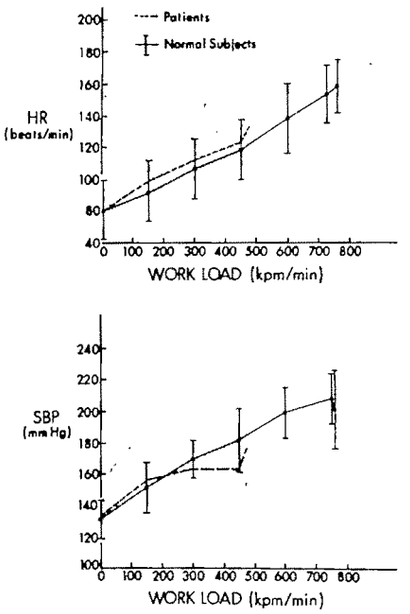

**FIGURE 5.** Changes in heart rate (HR) and systolic blood pressure (SBP) with increasing work load during upright bicycle exercise in 9 normal subjects and 17 patients with left ventricular failure. At comparable work loads, heart rate and systolic blood pressure were similar for each group. Normal subjects achieved higher work loads at a higher heart rate and systolic blood pressure than patients.

patients and normal subjects, indicating that comparable anaerobic end-points of exercise were achieved.

**Cardiovascular response to exercise:** Changes in heart rate, systolic blood pressure, and radionuclide indexes of cardiac function between rest and maximal exercise in all subjects are summarized in Table II. Responses to progressive exercise are illustrated in Figures 5 to 7. Heart rate responses during maximal exercise were lower in patients than in normal subjects ($p = 0.001$). A small difference in systolic blood pressure ($p > 0.05$) between the groups was also seen. The disparity between ejection fraction in patients and normal subjects was marked at maximal exercise ($p < 0.0001$). Patients has a significantly lower exercise/rest count output at maximal exercise than normal subjects ($p < 0.01$). The small differences in exercise/rest stroke counts and exercise/rest end-diastolic counts did not reach statistical significance, but the progressive data shown in Figure 6 suggest that patients had a diminished stroke count response despite a greater increase in end-diastolic counts during exercise. Changes in A-$VO_2$ from rest to maximal exercise were comparable in both groups.

**Determinants of maximal exercise performance:** The determinants of oxygen consumption can be expressed in the following equations: (1) $\dot{V}O_2$ = cardiac output·A-V oxygen difference; (2) Cardiac output =

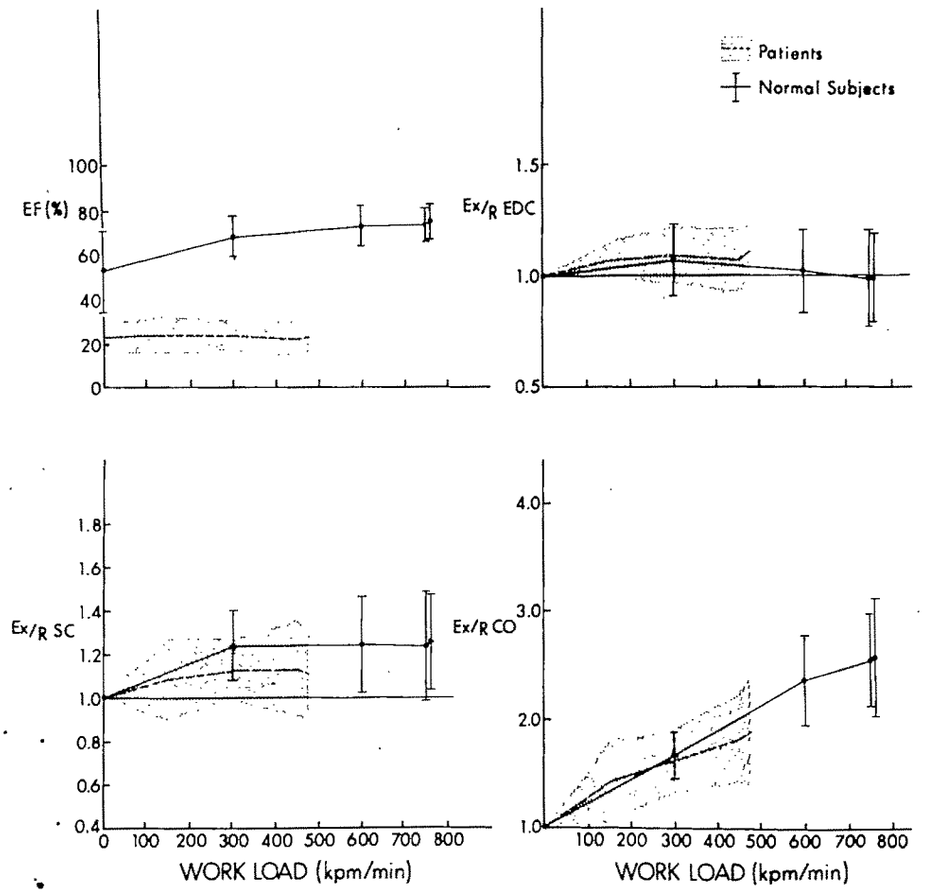

**FIGURE 6.** Changes in ejection fraction (EF), end-diastolic counts (EDC), stroke counts (SC), and count output (CO) with progressive upright bicycle exercise in 9 normal subjects and 17 patients with left ventricular failure. All values are represented as proportional changes from rest to exercise.

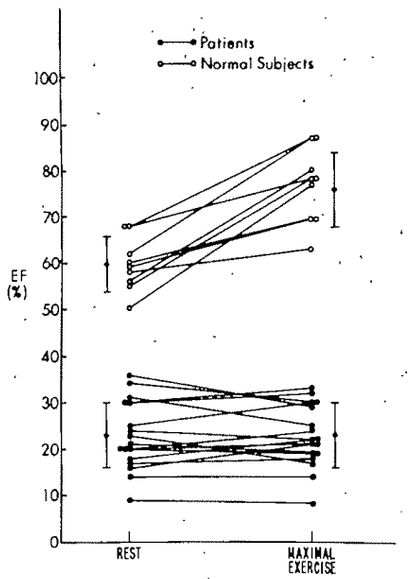

**FIGURE 7.** Changes in ejection fraction (EF) from rest to maximal upright bicycle exercise in 9 normal subjects (**open circles**) and 17 patients with left ventricular failure (**closed circles**). Mean values ± standard deviation are shown for group data.

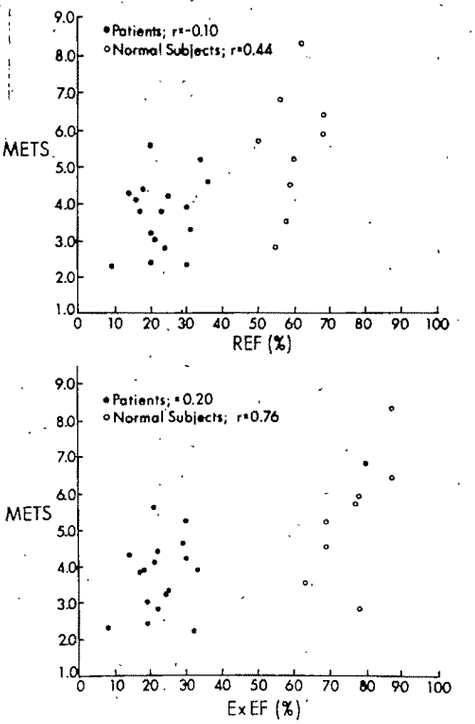

**FIGURE 8.** Relation between proportional change in oxygen consumption from rest to maximal exercise (Mets), and resting ejection fraction (REF, **upper panel**) and exercise ejection fraction (ExEF, **lower panel**). Correlations are seen for normal subjects (**open circles**), but not for patients with left ventricular failure (**closed circles**).

stroke volume (SV)·HR; (3) SV = end-diastolic volume (EDV)·EF; so that, (4) $\dot{V}O_2$ = EDV·EF·HR·A-$VO_2$. Maximal work performance in study patients and normal subjects was expressed as a multiple of resting oxygen consumption, that is, Mets = $MaxEx/_R$ $\dot{V}O_2$ = $MaxEx/_R$ EDC·$MaxEx/_R$ EF·$MaxEx/_R$ HR·$MaxEx/_R$ A-$VO_2$. Relations between Mets achieved and various factors that might influence exercise performance were examined in both study groups by univariate analysis; individual data are plotted in Figures 8 to 12. No correlation existed between age and Mets achieved in the study patients (r = 0.04) or the normal subjects (r = 0.20).

Despite the wide range of ejection fraction at rest and the variable response of the ejection fraction during exercise in patients, there was essentially no relation between either measurement and exercise performance as measured by Mets (Fig. 8) (r = −0.10 for rest and 0.20 for exercise ejection fraction). In normal subjects, resting ejection fraction was weakly related to Mets (r = 0.44, p >0.05). The relation between exercise ejection fraction and Mets was stronger (r = 0.76, p = 0.02). When the relation between Mets and proportional increases in ejection fraction from rest to maximal exercise was examined, a weak correlation could be demonstrated for normal subjects (r = 0.32, p >0.05), but not for patients (r = 0.10) (Fig. 9). In normal subjects, weak negative correlations were seen between exercise/rest stroke counts and Mets (r = −0.37, p >0.05) and between exercise/rest end-diastolic counts and Mets (r = −0.28, p >0.05) (Fig. 10); no correlation was seen in patients (r = 0.03 and 0.08, respectively). A positive correlation was observed between exercise/rest count output at maximal exercise and Mets in normal subjects (r = 0.65, p = 0.06) and in patients (r = 0.51, p = 0.03) (Fig. 11). Similar positive correlations were observed between $Ex/_R$ A-$VO_2$ and Mets in normal subjects (r = 0.83, p = 0.005) and in patients (r = 0.63, p = 0.01). Of the various determinants of cardiac output considered in patients, the strongest positive correlation with Mets was observed for exercise/rest heart rate (r = 0.57, p =

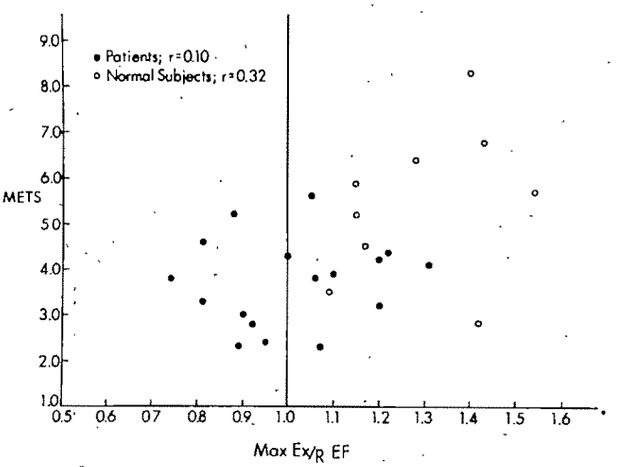

**FIGURE 9.** Relation between proportional change in oxygen consumption from rest to maximal exercise (Mets) and proportional change in ejection fraction (Max $Ex/_R$ EF) for normal subjects (**open circles**) and patients with left ventricular failure (**closed circles**).

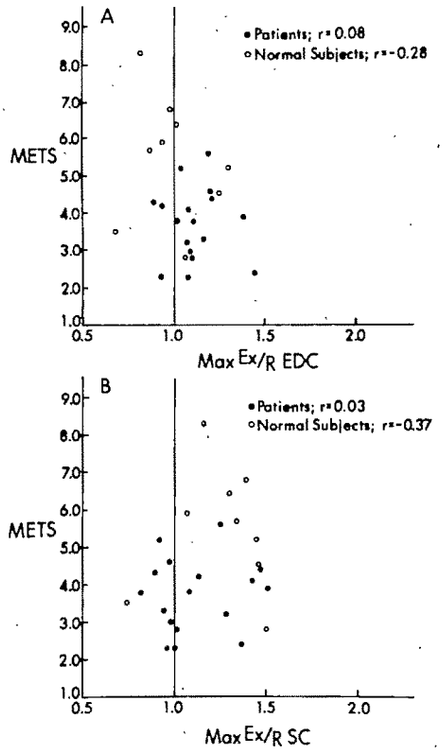

**FIGURE 10.** Relation between proportional change in oxygen consumption from rest to maximal exercise (Mets) and proportional changes in end-diastolic counts (Max $Ex/_R$ EDC, **upper panel**) and stroke counts (Max $Ex/_R$ SC, **lower panel**). Weak negative correlations are seen for normal subjects (**open circles**) but not for patients with left ventricular failure (**closed circles**).

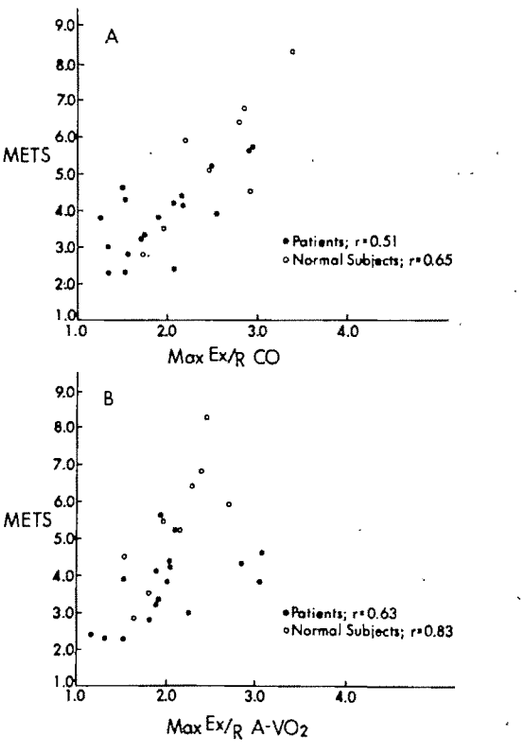

**FIGURE 11.** Relation between proportional change in oxygen consumption from rest to maximal exercise (Mets) and proportional changes in count output (Max $Ex/_R$ CO, **upper panel**) and arteriovenous oxygen difference (Max $Ex/_R$ A-$VO_2$, **lower panel**). Positive correlations are seen for normal subjects (**open circles**) and for patients with left ventricular failure (**closed circles**).

0.015) (Fig. 12). A positive correlation also was observed between Mets and heart rate in the normal subjects ($r = 0.50$), although this correlation was not significant for the small group.

Multivariable analysis of the determinants of Mets was carried out in 3 stages in the patients but not in the smaller group of normal subjects. The first stage combined $Ex/_R$ CO and $Ex/_R$ A-$VO_2$, the second combined $Ex/_R$ HR, $Ex/_R$ SC, and $Ex/_R$ A-$VO_2$, and the third included $Ex/_R$ HR, $Ex/_R$ EF, $Ex/_R$ EDC, and $Ex/_R$ A-$VO_2$ as possible determinants of Mets achieved during maximal exercise. This analysis demonstrated an approximately equal contribution to Mets achieved from $Ex/_R$ CO and $Ex/_R$ A-$VO_2$. It also confirmed the importance of $Ex/_R$ HR, but not $Ex/_R$ EF or $Ex/_R$ SC, as a determinant of Mets.

Two patients achieved normal or near-normal exercise performance as defined by a maximal value for Mets >5.0. The mechanism by which this was achieved can be seen from individual data in Figures 8 to 12. Although both patients had markedly abnormal ejection fractions at rest and during exercise, a normal or near-normal cardiovascular response to exercise was associated with a normal exercise/rest count output in each case. The patient who achieved the highest Mets (5.6) maintained a normal exercise/rest count output through normal stroke count and heart rate responses; the increase in stroke counts was achieved through an increase in end-diastolic counts, because EF did not change significantly. The patient who achieved the second highest value (5.2 Mets) did not increase stroke counts normally, but achieved a normal count output response through a compensatory increase in heart rate.

The mechanisms of achieving an adequate exercise performance in patients is further illustrated by the data from 5 patients who reached values of Mets between 4.0 and 5.0. Three of these patients doubled their count output by increasing ejection fraction and heart rate during exercise. The remaining 2 patients demonstrated a poor count output response but markedly increased arteriovenous oxygen difference.

## Discussion

Previous studies have demonstrated that patients with ventricular dysfunction have a highly variable exercise capacity.[1-3] However, the parameters that determine this variable exercise capacity have not been defined. Recent work by Benge,[1] Franciosa,[2,3] Port,[4] Conn,[7] and their co-workers has shown that resting left ventricular function correlates poorly with exercise performance. The present study was performed to correlate indexes of central and peripheral cardiovascular function measured at rest and during exercise with maximal upright bicycle exercise performance.

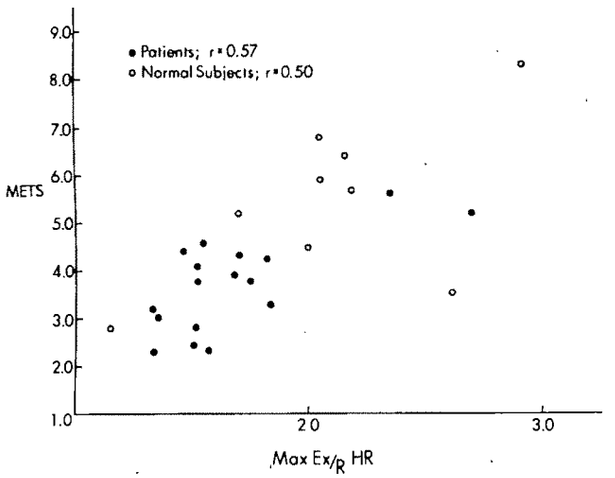

**FIGURE 12.** Relation between proportional change in oxygen consumption from rest to maximal exercise (Mets) and proportional change in heart rate (Max $Ex/_R$ HR) for normal subjects (**open circles**) and patients with left ventricular failure (**closed circles**). Correlations are seen for both groups.

**Methodology:** Oxygen consumption during maximal dynamic exercise involving at least 50% of total muscle mass is a measure of the functional capacity or reserve of the cardiovascular system.[8,9] Failure of the $\dot{V}O_2$ to rise with increasing work loads[8,10] has been used as objective evidence that maximal oxygen delivery and extraction have been achieved; however, such a plateau in the relation between $\dot{V}O_2$ and work load frequently is not attained in patients with cardiac dysfunction.[11,12] The ventilatory responses to metabolic acidosis are alternative indexes that maximal or near maximal oxygen consumption has been achieved.[5,6] Anaerobic endpoints of exercise can be calculated from measurements of ventilation, oxygen consumption, and carbon dioxide production, as described by Wasserman and McIlroy.[5] Subjects in the present study all achieved maximal or near-maximal exercise performance as defined by exercise to or above an anaerobic threshold.

For the purpose of analysis, exercise performance was expressed as a proportional change in oxygen consumption from rest to exercise, defined as Mets, rather than an absolute maximal $\dot{V}O_2$ measurement. Proportional changes in multiple variables of central and peripheral cardiovascular function from rest to exercise were thus related to Mets.

The measurement of ejection fraction by equilibrium radionuclide angiography is well established.[13–15] Several investigators[16,17] estimated left ventricular volumes by relating background-corrected counts in the left ventricular region at end-diastole to ventricular volume as determined by cardiac catheterization. Because variable tissue attenuation of radioactivity within the ventricular chambers may influence such measurements, we chose to use relative changes in left ventricular counts as a measurement of volume changes between rest and exercise. These measurements are independent of variable tissue attenuation but are dependent on the precision of measuring background-corrected end-diastolic counts. Duplicate measurements in the present study demonstrated a high degree of reproducibility for the estimations. The validation of this approach for examining changes in ventricular volume, cardiac output, and A-$VO_2$ during exercise is supported by studies in which noninvasive and direct measurements were made simultaneously in patients with left ventricular dysfunction.

**Determinants of maximal exercise performance:** *Normal subjects:* Cardiac output in normal subjects increases linearly with oxygen consumption, the increase varying 3- to 5-fold between rest and maximal exercise.[8,9,12,18–22] Heart rate appears to be the major contributor to the linear increase in cardiac output because increases in stroke volume reach a plateau at submaximal work loads.[8,19,20] The maximal change in stroke volume during exercise is a function of muscle mass and body position. Thus, Mitchell et al[9] reported an approximate doubling in stroke volume during maximal treadmill exercise, whereas Clausen et al[19,23] observed a 30% increase in the stroke volume during maximal leg exercise on a bicycle ergometer. Only slight increases in stroke volume may occur during maximal arm exercise.[19] Studies reporting no change or a minimal increase in end-diastolic volume during exercise[22,24] suggest that increases in stroke volume during exercise result from increases in ejection fraction.

Arteriovenous oxygen difference may increase as much as 3-fold in normal young subjects during maximal treadmill exercise; Mitchell et al[20] noted an increase in A-$VO_2$ which averaged 2.2 in normal young subjects at maximal treadmill exercise. The effect of physical training on the ability to widen A-$VO_2$ appears small: Clausen[23] reported that physical training increased maximal oxygen consumption by 17 to 18% in normal middle-aged volunteers; approximately 50% of the increase was attributed to a widening of the A-$VO_2$.

Data from our group of normal subjects are consistent with the preceding observations. Analysis of group data demonstrated increases in heart rate, systolic blood pressure, count output, and A-$VO_2$ with increasing work load. Statistical analysis demonstrated correlations between proportional change in heart rate, count output and A-$VO_2$ from rest to exercise, and the proportional change in oxygen consumption (Mets). The correlation between Mets achieved and the A-$VO_2$ response indicates that variable oxygen extraction was a determinant of the variable exercise performance. This is consistent with the expected variability in physical conditioning among these subjects.

*Patients:* As observed by Franciosa et al[2] and Epstein et al,[12] maximal oxygen consumption was markedly lower in our patients than in normal subjects. There was considerable variability between individual patients; although each patient exercised to an anaerobic endpoint, the proportional change in oxygen consumption at maximal exercise varied from 2.2 to 5.5 Mets. There was also considerable overlap of maximal oxygen consumption between normal subjects and patients with reduced ventricular function. The overall reduction in maximal oxygen consumption in patients resulted from a reduced maximal count output, because proportional

changes in A-$VO_2$ were comparable in normal subjects and patients. Reduced count output in turn appeared to result from a lower maximal heart rate and smaller increases in stroke counts during exercise; mean stroke counts increased 27% in normal subjects compared with 12% in patients. These findings are similar to those of Epstein et al,[12] who measured cardiac output, stroke volume, oxygen consumption, and A-$VO_2$ by cardiac catheterization during treadmill exercise in normal subjects and patients with functional class II to III heart failure. Compared with normal subjects, patients demonstrated lower maximal oxygen consumption, cardiac index, stroke volume, and heart rate. Despite a lower pulmonary arterial saturation at maximal exercise in patients than in normal subjects, maximal A-$VO_2$ and the proportional change in A-$VO_2$ from rest to exercise were similar in the 2 groups.

The present study provides additional information regarding the relation between indexes of central and peripheral cardiovascular function and the variable exercise capacity seen in patients with left ventricular dysfunction. Regression analyses demonstrated positive correlations between proportional changes in count output, A-$VO_2$, and heart rate and proportional changes in oxygen consumption. Multivariable analysis confirmed these findings and suggested approximately equal influences from count output and A-$VO_2$. The patients demonstrated a wide range of resting ventricular dysfunction. As observed by others,[1–4,7] there was essentially no correlation between resting ejection fraction and maximal oxygen consumption. Previous studies have not determined whether changes in ejection fraction during exercise contribute to the variable maximal exercise consumption. In the present study, neither the ejection fraction during exercise nor the proportional change in ejection fraction correlated with maximal oxygen consumption. There was no correlation between changes in either stroke counts or end-diastolic counts and maximal oxygen consumption.

As in normal subjects, the major cardiac determinant of variable exercise performance in patients was heart rate. Previous investigators have noted an attenuated heart rate response to exercise in certain patients with left ventricular failure[12,25] and have suggested that impaired autonomic function is responsible. This finding is supported by experimental data[26] and is consistent with our finding of reduced blood pressure response to exercise in these patients. The attenuated heart rate response in our patients was not age related, nor was it secondary to inadequate exercise performance because comparable anaerobic end-points were achieved in all patients.

The results of the present study confirm that patients with severe left ventricular dysfunction usually have a lower exercise capacity than normal subjects. Such patients have a low resting ejection fraction and a diminished ejection fraction response to exercise; many also have an inadequate chronotropic response to exercise. However, occasionally normal or near-normal exercise performance may be achieved by maintaining a normal cardiac output response through compensatory increases in end-diastolic volume or heart rate. The highly variable exercise performance among these patients is related predominantly to the variability in heart rate and A-$VO_2$ responses during exercise rather than to differences in the ejection fraction at rest or exercise or changes in stroke volume during exercise.

# Determinants of Ventricular Tachycardia in Patients With Coronary Artery Disease and Ventricular Aneurysm

## Clinical, Hemodynamic, and Angiographic Factors

MARC COHEN, MD, ISAAC WIENER, MD, AUGUSTO PICHARD, MD, JAMES HOLT, MA, HARRY SMITH, Jr., PhD, and RICHARD GORLIN, MD

**Many patients with coronary artery disease (CAD) in whom ventricular tachycardia (VT) develops have transmural scars or frank aneurysms. However, only a minority of patients with ventricular aneurysms go on to develop VT. To determine which factors are associated with the development of VT in patients with aneurysms, we retrospectively reviewed the records of 154 patients with CAD and segments of akinesia or dyskinesia, or both, on left ventriculography. Of the 154 patients, 85 had 24-hour Holter monitoring or 48 consecutive hours of continuous electrocardiographic monitoring in an intensive care unit within 6 months of catheterization. VT occurring at least 10 days after myocardial infarction (MI) or in the chronic phase was recorded in 19 patients (Group I); the remaining 66 patients did not have VT (Group II). The clinical, hemodynamic, and angiographic characteristics of these 2 groups showed no significant difference with respect to age, time from first transmural MI to catheterization, congestive heart failure (CHF), ejection fraction, or presence of dyskinesia. Patients with VT had significantly larger aneurysms and a higher prevalence of septal akinesia or dyskinesia. However, stepwise discriminant analysis revealed septal akinesia or dyskinesia to be the only independently significant variable distinguishing the 2 groups. Thus, septal involvement appears to be a major determinant of VT in patients with CAD and ventricular aneurysm.**

Previous studies in patients with CAD and VT indicate that tachycardia often arises in the setting of multivessel disease and ventricular aneurysm.[1–5] However, VT develops in only a minority of patients with ventricular aneurysms.[7–9] The factors responsible for the development of this tachycardia in the presence of ventricular aneurysm have not been determined.

This study retrospectively reviews the clinical, hemodynamic, and angiographic characteristics of 85 patients with ventricular aneurysm secondary to CAD. In 19 of the 85 patients ventricular tachycardia developed during Holter or intensive care unit monitoring. Characteristics of the patients with VT were compared with those of patients without evidence of this arrhythmia.

### Methods

The records of 708 patients who underwent coronary arteriography and biplane left ventriculography at Mount Sinai Hospital in 1979 were retrospectively reviewed. Catheterization was accomplished by the Sones or Judkins technique and included selective coronary arteriography, right and left anterior oblique left ventriculography, measurement of left ventricular end-diastolic pressure, and calculation of the ejection fraction of the left ventricle in the right anterior oblique plane. Patients without a left anterior oblique plane ventriculogram were excluded from this study. CAD was diagnosed when at least 1 major coronary artery had a stenotic lesion causing ≥50% reduction in luminal diameter. Ventricular aneurysm was diagnosed when either right anterior oblique or left anterior oblique left ventriculography, or both, demonstrated a segment of akinesia or dyskinesia involving ≥10% of the total diastolic perimeter.[10] Because most aneurysms did not bulge from the residual myocardial segments in diastole, the silhouettes of the left ventricle in systole and diastole were superimposed so as to allow approximation of the length of the aneurysmal segment in diastole. Once obtained, this length was expressed as a percentage of the total diastolic perimeter in a manner similar to that described by Field et al.[11] Five possible locations of aneurysmal segments were identified: anterior, apical, and inferior from the right anterior oblique view and septal or posterolateral from the left anterior oblique plane. In addition, aneurysmal segments were described as either retaining or having lost their trabeculations.

A ventricular aneurysm was found in 154 patients with CAD. The complete inpatient chart, the catheterization report, and the attending physician's office chart of these 154 patients were reviewed. Within 6 months of catheterization,

LAD = left anterior descending artery; LMCA = left main coronary artery; LVEDP = left ventricular end-diastolic pressure; NS = not significant; RAO = right anterior oblique; RCA = right coronary artery.

85 patients had either 24-hour Holter monitoring (26 patients) or continuous electrocardiographic monitoring in an intensive care unit for at least 48 consecutive hours (59 patients). This study is based on the characteristics of these 85 patients.

VT (3 or more consecutive ventricular ectopic beats) occurred in 19 patients at least 10 days after MI or in the chronic phase of ischemic heart disease (Group I). Sixty-six patients had no ventricular arrhythmias or ventricular arrhythmias other than VT such as isolated premature contractions or bigeminy (Group II). Patients with VT during the acute phase of MI or during an episode of transient MI, digoxin toxicity, or significant electrolyte or metabolic derangement were excluded from the analysis.

Clinical, hemodynamic, and angiographic characteristics were recorded in each of the 85 patients. The clinical variables recorded were age, sex, history of diabetes mellitus, hyperlipidemia, hypertension, cigarette smoking, presence of active angina, number of previous MIs, time from first MI to catheterization (an indirect estimate of the age of the aneurysm), presence of clinical signs and/or symptoms of CHF, cardiomegaly by chest X-ray, and presence of pathologic Q waves on the electrocardiogram. The hemodynamic variable recorded for each patient was left ventricular end-diastolic pressure. The angiographic variables studied were the percentage of stenosis and location of obstructions in each major coronary artery. Patients with disease of the left anterior descending artery were further classified as having the stenosis before or after the first septal perforator. In addition, the total number of vessels with ≥50% stenosis was recorded for each patient. Data derived from left ventriculography included calculation of ejection fraction and identification of any akinetic and dyskinetic segments, percentage of perimeter involved, location of aneurysmal segments, and presence or absence of trabeculation in the endocardial surface of the aneurysm.

Of the 19 patients in Group I, 2 were receiving digoxin alone, 6 digoxin and a diuretic, and 11 an antiarrhythmic drug (quinidine in 7, pronestyl in 3, and Norpace in 1). In Group II, 3 patients were receiving digoxin alone, 4 a diuretic agent alone, and 20 digoxin and a diuretic drug. The small number of patients within each of these subgroups precluded meaningful comparisons.

**Statistical methods:** The characteristics of the patients with VT were compared with those of patients without VT. The 2 groups of patients were compared for all continuous and discrete variables using $t$ and chi-square tests, respectively. A p value ≥0.05 was considered not significant. A stepwise discriminant analysis was performed to determine which variable best discriminated between the 2 groups.

The data analyzed were derived from the subset of 85 patients who met the qualifying criteria on the basis of biplane angiography, electrocardiographic monitoring, and so forth. Inferences based on these data are made with some reservation. In addition, given our sample size, the power of our method to detect as significant a difference of 20% between the 2 groups, was about 65%, that is, the beta error was approximately 35% at an alpha of 5%.

## Results

**General population:** In Group I, VT occurred in the late hospital phase of an acute MI in 5 patients and in the chronic phase in 14 patients. Recurrent sustained VT was documented in 3 patients, recurrent nonsustained VT in 9, and an isolated episode of nonsustained VT in 7. Three patients in Group I had an episode of ventricular fibrillation in addition VT.

In Group II, 2 patients had frequent ventricular premature contractions (≥15/h) with rare couplets, 5 had frequent ventricular premature contractions with occasional runs of bigeminy or trigeminy, and 54 had infrequent multiform or uniform ventricular premature contractions, or both. Five patients had no ventricular arrhythmia.

**Clinical characteristics:** The clinical characteristics of the 2 groups of patients are compared in Table I. There was no significant difference between Groups I and II with respect to sex, number of previous MIs, time between the first MI and cardiac catheterization, presence of CHF, cardiomegaly on chest X-ray, or the presence of Q waves on the electrocardiogram. In addition, there was no significant difference between the 2 groups with respect to a history of diabetes mellitus, hypertension, hyperlipidemia, or smoking. However, patients in Group I were significantly younger than those in Group II, although this difference did not remain significant after stepwise discriminant analysis. Patients with VT had a significantly lower prevalence of active angina at the time of study.

**TABLE III Characteristics of the Aneurysmal Segments Identified by Left Ventriculography**

| | Group I (VT) | Group II (No VT) | p |
|---|---|---|---|
| Size of aneurysm (mean % of perimeter) | 40 ± 12 | 32 ± 14 | <0.02* |
| Akinesia (%) | 100 | 95 | NS |
| Dyskinesia (%) | 47 | 28 | NS |
| Septal akinesia or dyskinesia (%) | 89 | 42 | <0.002† |
| Anterior akinesia or dyskinesia (%) | 53 | 32 | NS |
| Apical akinesia or dyskinesia (%) | 79 | 64 | NS |
| Inferior akinesia or dyskinesia (%) | 47 | 67 | NS |
| Posterolateral akinesia or dyskinesia (%) | 5 | 3 | NS |
| Trabeculations preserved (%) | 0 | 8 | NS |

* Difference does not remain significant after stepwise discriminant analysis. † Difference remains significant after stepwise discriminant analysis.

**Hemodynamics and coronary arteriography:** The hemodynamic and coronary arteriographic characteristics of the 2 groups are shown in Table II. There was no significant difference between Groups I and II with respect to left ventricular end-diastolic pressure or right anterior oblique ejection fraction. The mean left ventricular end-diastolic pressure was elevated in both groups, and the mean ejection fraction was slightly depressed in both.

Coronary arteriography revealed that patients in Group I had a significantly smaller number of vessels with ≥50% stenosis (1.9 ± 0.5 versus 2.3 ± 0.7, p = 0.03). This difference was observed because patients in Group I had a significantly lower mean percentage of narrowing of the circumflex artery than did patients in Group II (44 ± 39% versus 69 ± 32%, p <0.006). No significant difference between the 2 groups was detected with reference to the other coronary arteries. The frequency with which significant stenosis of the left anterior descending artery occurred before the first septal perforator did not differ significantly in the 2 groups.

**Left ventriculography:** The characteristics of the aneurysmal segments in both groups as identified from the left ventriculogram are shown in Table III. The mean size of the aneurysms, measured as a percentage of the diastolic perimeter, was significantly larger in patients in Group I than in Group II (40 ± 12% versus 32 ± 14%, p <0.02); however, this difference did not remain significant after stepwise discriminant analysis. A higher percentage of patients in Group I had dyskinetic segments; however, this difference did not reach statistical significance. Akinesia or dyskinesia occurred with a significantly higher frequency in the septal region in Group I patients (89 versus 44%, p <0.002). No significant differences were detected with respect to the other 4 locations. Eighty of the 85 patients had aneurysmal segments without normal endocardial trabeculation; the 5 patients with preserved endocardial trabeculation were all in Group II.

Stepwise discriminant analysis revealed that septal involvement was the most important variable differentiating Group I from Group II. The second most important factor was the difference in the degree of circumflex disease.

## Discussion

VT in the setting of CAD and ventricular aneurysm was first described in 1934.[12,13] Since then, a close association between malignant ventricular arrhythmias and ventricular aneurysm has been well established.[1–9,14–16] Despite these observations, however, only a minority of patients with ventricular aneurysm appear to develop VT.[7–9] Factors that predispose certain patients with aneurysms to VT are yet to be identified.

Previous work by our group showed that certain electrophysiologic abnormalities differentiated patients with aneurysm and VT from those with aneurysms without VT.[17] In the present study we examined clinical, hemodynamic, and angiographic characteristics to identify additional variables that might predispose a patient with aneurysm to VT. None of the clinical or hemodynamic characteristics we evaluated were able to distinguish between patients with and those without VT. Patients with VT had a lower incidence of active angina and less severe CAD secondary to less severe disease in the circumflex artery.

Septal akinesia or dyskinesia was the most important angiographic variable differentiating between the 2 groups of patients. Septal involvement correctly identified 89% of the patients with VT, whereas 58% of the patients without VT did not have septal involvement.

In a review of 109 patients with ventricular aneurysm secondary to CAD, Rochemaure et al[8] found that 8 of 39 patients (21%) with large aneurysms (>6 cm in diameter at autopsy) had VT. In contrast, only 1 of 48 patients (2%) with a medium or small aneurysm developed VT. Mourdjinis et al[9] observed that 6 of 10 patients with "large" aneurysms developed malignant ventricular arrhythmias, whereas none of the 29 patients with "minor" aneurysms developed malignant arrhythmias. In agreement with the findings of these investigators, our patients who had VT tended to have larger aneurysms than did patients without tachycardia. However, the size of the aneurysm did not distinguish between the 2 groups once septal involvement was taken into account in the multivariate analysis. Although septal akinesia or dyskinesia frequently occurs in the presence of a large aneurysm, 3 patients had large aneurysms that did not involve the septum and none appeared to have VT.

The importance of the location of aneurysmal segments was apparent in a previous study by Wiener et al.[17] All of their patients with ventricular aneurysms and VT had fragmented activity along the septal border zone of their aneurysm. In contrast, fragmented activity along the septal border was rarely observed in their patients with aneurysms who did not have VT. Horowitz et al[18] identified the septum as the source of sustained VT in almost half of their 29 patients operated on for this arrhythmia. Our finding of a significantly higher incidence of septal akinesia or dyskinesia in patients with clinically identified VT is consistent with these mapping studies. Septal involvement may be important in the development of ventricular arrhythmia because of the high density of Purkinje fibers in the ventricular septum. Alternatively, because the septum usually receives a dual blood supply, some

muscle or Purkinje fibers rendered ischemic by occlusion of 1 coronary artery may be maintained by flow from the other coronary artery and become a focus of electrical instability.

Septal involvement occurs frequently in patients with CAD and ventricular aneurysm. Of our original cohort of 154 patients with aneurysms, 40% had septal scars. Indeed, 42% of our patients without VT had septal involvement. Some of these patients may have had VT that we were unable to detect. Patients were monitored at different times in the course of their disease, in addition, we relied on 48 hours of intensive care unit monitoring as a substitute for Holter monitoring. Lastly, we now appreciate that 24-hour Holter monitoring might be insufficient to detect malignant ventricular arrhythmias.[19,20]

Two patients with an angiographically normal septum had VT. The correlation between angiographic and pathologic evidence of septal scarring is not well established. Patients with a small scar in the septal region may appear to have normal septal wall motion on angiography. In addition, superimposition of the shadow of an apical aneurysm may obscure the septum. Therefore, factors in addition to septal involvement must be involved in the genesis of VT.

Other than septal involvement, the only variable differentiating between patients with and those without VT was the degree of circumflex disease. Why patients with VT generally have less severe circumflex disease than do patients without VT is not apparent. This may be a chance observation secondary to sampling error. Therefore, our group of patients with VT, 89% of whom have septal scars, may be biased with respect to severe circumflex disease.

Recently, Bulkley et al[21] suggested that endocardial disease may be an important variable differentiating patients with aneurysms in whom VT develops from those in whom it does not.[18] Specifically, VT developed in 10 of 13 patients with endocardial fibroelastasis and little or no mural thrombus, whereas VT developed in only 2 of 10 patients with mural thrombus. Our study did not review pathologic data.

**Clinical implications:** Analysis of the clinical, hemodynamic, and angiographic characteristics of 85 patients with ventricular aneurysm suggests that septal involvement is a major determinant of VT. Prospective studies in patients with myocardial scars are needed to correlate angiographic observations with the development of ventricular arrhythmias. Angiographic data from this study together with the electrophysiologic observations of Wiener et al[17] suggest that surgical intervention for refractory ventricular arrhythmias should include intraoperative assessment of the ventricular septum.

# Relation of Exercise to the Recurrence Rate of Myocardial Infarction in Men

## Ontario Exercise-Heart Collaborative Study

PETER A. RECHNITZER, FRCP(E), DAVID A. CUNNINGHAM, PhD, GEORGE M. ANDREW, PhD, CAROL W. BUCK, MD, NORMAN L. JONES, FRCP, TERENCE KAVANAGH, FRCP(C), NEIL B. OLDRIDGE, PhD, JOHN O. PARKER, FRCP(C), ROY J. SHEPHARD, MD, JOHN R. SUTTON, FRCP(C), and ALLAN P. DONNER, PhD

**The Ontario Exercise-Heart Collaborative Study was a multicenter randomized clinical trial of high intensity exercise for the prevention of recurrent myocardial infarction in men. The 4-year recurrence rate among 379 patients on a program of high intensity exercise did not differ significantly from that among 354 control patients on a program of light exercise, despite the greater reduction in heart rate in the former group. The relative odds of recurrence in the high intensity group were 1.09, with 95% confidence limits of 0.61 and 1.96.**

Recent epidemiologic studies[1,2] have shown that physical activity is associated with a reduced incidence of coronary disease, although the association was not strong.[3] However, these studies are used to some extent as the rationale for exercise in the prevention of recurrence in patients who have had myocardial infarction. A retrospective analysis suggested that this approach might have value,[4] but in prospective studies carried out in Sweden[5] and the United States[6] the results have been equivocal, although a group in Finland[7] reported a significantly lower incidence of early sudden death in a group with a multifactorial approach which included an exercise prescription.

The Ontario Exercise-Heart Collaborative Study[8] was designed as a randomized clinical trial to determine whether a program of high intensity exercise was associated with a lower rate of reinfarction than a program of light exercise, insufficient to produce a training effect on the cardiovascular system, but which controlled for a possible group therapy effect seen by various investigators after myocardial infarction.[9,10]

The design of the study has been described in detail elsewhere.[8] Its objective was to test the hypothesis that over a 4-year period a 50% reduction in the recurrence of infarction could be achieved by a high intensity exercise program. Such a reduction would be of a definite clinical significance, and a study to test this hypothesis was shown to be feasible in an uncontrolled study carried out by Rechnitzer et al.[4] Although a smaller degree of reduction in the recurrence rate might be of clinical importance, the number of subjects required to demonstrate a positive effect would be inordinately large.[11]

The best baseline rate of recurrence available at the beginning of the trial was that of 22% reported by Weinblatt et al[12] from the HIP study in New York. Therefore, sample size calculations were based on detecting a 50% reduction in recurrence (from 22 to 11%), with a Type I error of 0.05, Type II error of 0.10, and an anticipated dropout rate of 35%.

The trial began in 1972 as a 4-center collaborative clinical trial, but was enlarged in 1974 to include 3 additional centers because the observed dropout rate exceeded that on which the power calculation of the original design was based. The former are referred to as the "major" centers and the latter as the "satellite" centers.

Participating Centers (all in Ontario, Canada): McMaster University, Hamilton; Queen's University, Kingston; University of Ottawa, Ottawa; University of Toronto and Toronto Rehabilitation Center, Toronto; University of Waterloo, Waterloo; University of Western Ontario, London; and University of Windsor, Windsor. This project was supported by Research Grant PR263 from the Ontario Ministry of Health, Toronto, Ontario, Canada. Manuscript received January 26, 1982; revised manuscript received July 2, 1982, accepted July 2, 1982.

Address for reprints: Peter A. Rechnitzer, FRCP(E), 450 Central Avenue, Suite 304, London, Ontario, N6B 2E8 Canada.

## Methods

A total of 733 male subjects participated in the study, 706 patients having had a myocardial infarction between 2 and 12 months and 27 patients between 13 and 17 months before entry. The subjects ranged in age from 26 to 56 years.

All subjects had at least 2 of the following diagnostic criteria: typical chest discomfort, a significant increase in cardiac enzyme levels (serum glutamic oxalacetic transaminase, creatine phosphokinase), or electrocardiographic changes compatible with a transmural or subendocardial infarction. Additional eligibility criteria were the following: (1) absence of cardiac failure; (2) absence of diabetes or controlled diabetes, not insulin-dependent; (3) diastolic blood pressure ≤110 mm Hg, but possibly receiving antihypertensive medication; (4) absence of any orthopedic disability that would limit progressive physical activity; (5) absence of significant airway obstruction in spirometric measurements ($FeV_1/VC \geq 60\%$); (6) consent of the family physician and a signed informed consent by each subject for entrance into the study.

The subjects were placed on high intensity exercise (HIE) or low intensity exercise (LIE) by stratified random allocation. The stratifying variables were (1) presence or absence of hypertension, defined as 3 readings >160 systolic or 90 diastolic, or both; (2) blue collar versus white collar employment; (3) presence or absence of angina; (4) Type A versus Type B behavioral pattern as measured by the standardized interview technique of Rosenman.[13]

* Incorrectly diagnosed, baseline data only. † Totals are not always 100% because of rounding errors. ‡ Based on the 427 subjects who had complete lipid determinations.

Medical examination at entry included measurement of height, weight, and skinfold thickness; electrocardiography; hemoglobin, fasting plasma glucose, cholesterol, and triglyceride determinations; and a chest X-ray if one had not been taken at the time of discharge from hospital. Table I shows that the baseline characteristics had very similar distributions in the HIE and LIE groups.

**Exercise test protocols:** The exercise test protocols have been described in detail elsewhere.[8] The Stage 1 test, a progressive incremental load test carried out on a cycle ergometer, was used to determine the exercise prescription. A Stage II test, a steady state exercise test carried out on a cycle ergometer, was also used at the major centers to determine cardiac output and other physiologic responses to exercise.[14] The tests were repeated at 6 months, at 12 months, and at 12-month intervals thereafter. Quality control data on the exercise measurements were collected regularly and the measured values were found to be reproducible.[15]

For each individual, a regression equation relating heart rate to oxygen uptake (4 major centers) or approximated oxygen uptake (3 satellite centers) was calculated by the least-squares method. The heart rate and oxygen uptake of 1.25 liters·min$^{-1}$ or 82 W (approximately 1.25 liters·min$^{-1}$) were derived from this equation ($HR_{1.25}$). In the HIE and LIE groups, 10 and 11% of the patients, respectively, were receiving beta-blocking drugs. Subjects in the HIE program on beta-blocking drugs were tested twice, once 48 hours after medication was stopped to determine the training response and once on medication to calculate the exercise prescription. Subjects in the LIE program were tested after medication was stopped.

**Training regimens:** The HIE subjects (n = 379) met regularly for a program of endurance training. They carried out an exercise prescription based on the subject's graded exercise test results.[16] The exercise prescription was calculated to give a walking or jogging pace requiring between 65 and 85% of the subject's estimated maximal oxygen uptake. After an introductory period of 8 weeks, the subjects were asked to supplement the supervised sessions (twice weekly in 6 centers, once weekly in 1 center) by carrying out the same exercise prescription on their own for a total of at least 4 times per week. Pulse counts were taken by the subjects during both the supervised and the unsupervised sessions to ensure reaching the prescribed exercise heart rate. Exercise tests were repeated after 8 weeks for review of the exercise prescription; thereafter, exercise tests were carried out every 6 months or more frequently if clinically indicated.

The LIE subjects (n = 354) met at least once a week for relaxation and supervised recreational activities such as volleyball, bowling, or swimming. The activities were structured to produce minimal training; at least 3 pulse counts were taken during each session to ensure that the patient's exercise intensity was not associated with a heart rate greater than observed at 50% of the estimated maximal oxygen uptake. The supervised sessions in both the HIE and the LIE groups lasted approximately 1 hour.

All supervised sessions included the attendance of a physician and the immediate availability of cardiopulmonary resuscitation equipment; exercise leaders were trained in cardiopulmonary resuscitation, and rapid communication with ambulance services was established.

Meetings of the supervisory personnel were held regularly to discuss the regimens of the 2 groups; in addition, 1 of the supervisory personnel visited each participating center annually to ensure that the class format for both the HIE and the LIE groups was uniform. Both HIE and LIE participants at all centers were encouraged to stop smoking and control obesity. If a subject's serum lipid level was abnormal, he was informed and advised to see his family physician. A standard letter to the physician reported cholesterol and triglyceride values and included suggestions for appropriate dietary control.

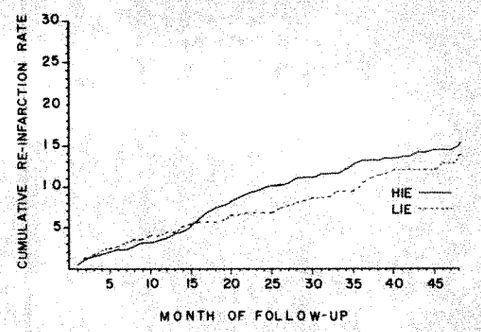

**FIGURE 1.** Cumulative dropout rates by month in HIE and LIE subjects over the 4-year intervention period.

There was no obvious contamination of the 2 groups. Although in some instances the instructors were common to both groups, the HIE and LIE groups met on separate occasions and took little interest in each other's activities. All subjects were asked to fill out an activity questionnaire at yearly intervals. Samplings of these questionnaires showed that the proportion of LIE subjects who were engaging in regular, vigorous exercise was less than 5%.

**Follow-up study:** Each follow-up assessment included an interim clinical history, a 12-lead resting electrocardiogram, and an exercise test. Of the 733 eligible subjects who entered the study, the potential follow-up period was 4 years in 450 subjects, 3 to 4 years in 225 subjects, and 2 to 3 years in 58 subjects. The mean follow-up period for all subjects was 3.3 years.

Patients who failed to appear for 3 consecutive activity sessions were contacted by telephone and encouraged to attend. If a patient did not attend a single session for 8 weeks, he was normally considered a dropout and was notified. Thirty-two subjects with coronary bypass and 3 who died from noncoronary disease were not classified as dropouts, because these reasons had no bearing on the subject's willingness to continue in the study.

The overall dropout rate was 45.4% (45.9% in the HIE and 44.9% in the LIE group). The characteristics on entry of the subjects who subsequently dropped out were similar to those of the groups to which they were originally allocated (Table I). The cumulative life table presentation (Fig. 1) demonstrates that most of the subjects who dropped out did so in the first year of the study. At the conclusion of the study, dropouts were traced to ascertain whether reinfarction had occurred. Reported recurrences were verified from medical records using the study criteria for infarction. Of the original 733 patients entered into the study, 92.4% were successfully traced.

## Results

The number of fatal and nonfatal reinfarctions in the HIE group were 15 and 39, respectively, and in the LIE group, 13 and 33. Thus, the proportion of fatal reinfarctions in the 2 groups (27.8% in the HIE and 28.3% in the LIE group) was very similar. Because the number of fatal reinfarctions was small, they were combined with nonfatal reinfarctions in the analyses of outcome. The overall reinfarction rates in the HIE and LIE groups were 14.2 and 13.0%, respectively.

**TABLE II Life Table Comparison of Reinfarction Experience in High and Low Intensity Exercise Groups, Including Dropouts in the Group to Which They Were Allocated**

| Follow-Up Year | Group | n | Reinfarctions* in Follow-Up Year (n) | Cumulative Results: Life Table Probability of Reinfarction Before End of Year | Cumulative Results: Relative Odds of Reinfarction in HIE/LIE Groups |
|---|---|---|---|---|---|
| 1 | HIE | 379 | 16 | 0.04 | 0.93 |
| | LIE | 354 | 16 | 0.05 | |
| 2 | HIE | 353 | 22 | 0.10 | 1.50 |
| | LIE | 330 | 8 | 0.07 | |
| 3 | HIE | 296 | 9 | 0.13 | 1.18 |
| | LIE | 283 | 14 | 0.11 | |
| 4 | HIE | 189 | 3 | 0.14 | 1.09† |
| | LIE | 187 | 6 | 0.14 | |

* Four reinfarctions in the HIE and 2 in the LIE group are not shown in this table because they occurred in the last fractional year of follow-up study for the subject involved.[17] To recapture this information, the analysis was redone using months rather than years as the follow-up interval. This analysis yielded virtually identical results. † 95% confidence limits, 0.61 to 1.96.

Table II gives the outcomes for the HIE and LIE groups calculated by a life table method.[17] The cumulative life table reinfarction rates are plotted in Figure 2. At each year of follow-up study, the outcome for LIE was, with 1 exception, slightly better than that for HIE. At the fourth year of follow-up study, the relative odds ratio of reinfarction in the HIE group was 1.09. The lower 95% confidence limit for this odds ratio is 0.61,[18] corresponding to a reduction of 39% in the risk of reinfarction.

The question arises as to whether the HIE group achieved the intended degree of cardiovascular training. The heart rate reduction at 1.25 liters·min$^{-1}$ at the end of 1 year was 5.2 ± 15.91 in the HIE group and 2.0 ± 14.73 in the LIE group. At the end of 4 years the heart rate reduction was 10.2 ± 13.39 in the HIE group and 4.0 ± 13.46 in the LIE group. Because the reduction was significantly greater in the HIE group than in the LIE group at 4 years ($p = 0.01$), it is reasonable to conclude that the exercise experience of the 2 groups was different.

In a trial with a high rate of dropouts, the full effect of an experimental intervention is bound to be diluted when the analysis retains dropouts in the group to which they were allocated. However, if an analysis were to exclude dropouts and the results were not more favorable for the intervention group, it would be reasonable to conclude that there was little treatment effect to be diluted. This, in fact, was what we found. When the life tables were recalculated to exclude subjects after the date of dropout, the relative odds for HIE/LIE were 1.24, with 95% confidence limits of 0.66 and 2.34. A third life table analysis, which compared the reinfarction experience in the 2 groups excluding dropouts entirely, resulted in a relative odds of 1.22. Although it would be improper to draw any conclusions about the treatment effect if these secondary analyses had shown an advantage of HIE, the absence of such an advantage reinforces the impression that a program of HIE had no specific effect in preventing reinfarction. Reinfarction rates among HIE droputs (11.5%) and LIE dropouts (12.6%) were very similar.

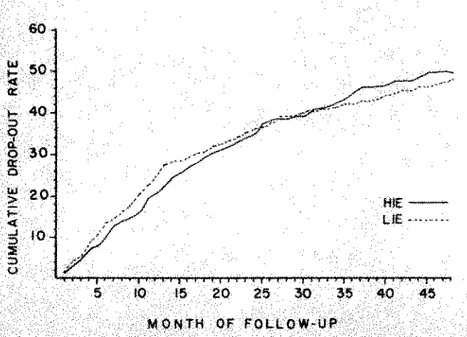

**FIGURE 2.** Cumulative reinfarction rates by month in HIE and LIE subjects over the 4-year intervention period.

Because this was a multicenter trial, 2 other observations are relevant. The first is that no significant differences existed in the overall rate of reinfarction among the 7 participating centers. The second is that in none of the centers was there a significant difference between the HIE and the LIE groups in the rate of reinfarction.

## Discussion

Exercise programs have become popular for rehabilitation after myocardial infarction,[19] but the justification in terms of a reduction in morbidity and mortality is still debated. Before the inception of this study, reports of exercise in cardiac rehabilitation were retrospective, nonrandomized, or lacked stratification for known risk factors.[4,20,21] The Ontario Exercise-Heart Collaborative Study was designed to circumvent some of these problems by prospectively investigating the effects of exercise training using a stratified randomized allocation to treatment groups.[8] When the trial was designed, the possibility of having an observed-only control group, in addition to an LIE group, was considered, but the available pool of subjects was insufficient to permit a 3-group trial Therefore, it was decided to have only a placebo control group on the grounds that the primary objective was to determine the specific ef-

fect of an HIE program designed to produce an improvement in cardiovascular fitness over and above any placebo effect associated with group membership.[9,10]

To determine whether an exercise training program would affect recurrence rates in postinfarction men, we decided that the subjects would have a reasonable chance of being trainable if the entry age were under 56 years. The randomization was stratified to control prognostic factors known to be important at the time the study began, that is, hypertension, angina, Type A behavioral pattern, and social class.

Although the dropout rates were high, they were nearly identical in the 2 groups; the relevant characteristics of dropouts were similar in the HIE and LIE groups (Table I), and the high follow-up rate of 92.4% allowed identification of the reinfarction status of the great majority of dropouts.

Previous clinical trials of the role of exercise in reducing the reinfarction rate in Sweden[5] and the United States[6] demonstrated no significant difference in reinfarction between exercise and control groups but suggested that there were considerable physiologic and psychologic benefits of the exercise regimen. A recent study carried out in Finland[7] indicated that the rate of sudden death may be reduced in a group receiving a multifactorial intervention program including exercise. Our results tend to confirm the observations made in Sweden[5] and the United States.[6] However, our study, by comparing 2 different levels of exercise intensity, extended these observations and suggests that LIE together with the social support of group membership previously reported as being beneficial[9,10] has an effect equivalent to that of an aggressive exercise prescription centered around jogging.

Why was the rate of reinfarction lower than expected, in advance of the trial, in both groups? Perhaps the medical criteria for entry, plus an element of self-selection, drew into the study patients with a more favorable prognosis. The close medical supervision and the social support entailed in such a program might have been considered contributory factors. However, the low recurrence rate in the control group of the American study[6] in which these features were minimal makes this unlikely.

Our results indicate that an HIE program compared with one designed to produce a minimal training effect does not reduce the risk of reinfarction. The lower 95% confidence limit for the relative odds ratio of high to low intensity exercise was 0.61, indicating that the hypothesized 50% reduction in the risk of reinfarction is highly unlikely. Two views may be taken of these results, depending on one's attitude toward the degree of benefit that would be worthwhile detecting. If a reduction of less than 50% in the risk of reinfarction is not considered to be worth the effort and expense of mounting an HIE program, we would be inclined to regard the results of this study as useful. However, if a lesser degree of benefit is deemed to be worth the cost of attainment, the present study must be considered inconclusive.

This study addresses the effect of exercise on the risk of reinfarction only. The potential long-term benefit of this type of intervention on the quality of life remains to be measured.

**The Ontario Exercise-Heart Collaborative Study was a multicenter randomized clinical trial of high intensity exercise for the prevention of recurrent myocardial infarction in 733 men. Of the 678 subjects who could have participated for at least 3 years, 315 (46.5%) dropped out. Stepwise multiple linear logistic regression analysis was carried out to examine the relation between subject characteristics and the probability of dropping out during the study. Analysis was performed on the entry group as a whole by considering those subjects who had reinfarction while complying with the program and also by excluding all subjects with reinfarctions. The consistent and statistically significant predictors of dropout in both analyses were *smoking* and a *blue collar occupation.* Angina was significantly associated with dropout only when reinfarctions were excluded. It may be important to consider these factors when investigating the potential for compliance-improving strategies in reducing dropout from exercise rehabilitation programs.**

Retrospective nonexperimental studies of physical conditioning have suggested that exercise may reduce the rate of recurrent myocardial infarction.[1] However, these studies may be flawed by membership bias and other design weaknesses[2]; prospective clinical trials in which patients were randomly allocated into exercising and control groups have shown little evidence of a lower recurrence of myocardial infarction in the exercising group than in the control group.[3–6] However, these randomized studies have been weakened by a high rate of dropout.[3–7]

The Ontario Exercise-Heart Collaborative Study (OEHCS) was an experimental study of the effect of physical conditioning on reinfarction, in which subjects were stratified by risk factors and then randomized into high and low intensity exercise groups.[8] As compliance with long-term exercise rehabilitation programs was suspected to be a potential problem, 1 objective was to investigate dropout from the 2 groups. If a potential dropout can be identified at entry, it may be feasible to initiate compliance-improving strategies. Interim observations on the characteristics of the potential dropout in the OEHCS have been reported[7]; the present analysis deals with observations made between 1972, when the study was initiated, and 1979, when the study was completed.

### Methods

**Subjects:** From initial screening procedures, described elsewhere by Rechnitzer et al,[6,8] 733 patients entered the study, of whom 678 were followed up for ≥3 years; 46 patients were lost to follow-up for reinfarction status (because of surgical intervention or because they could not be traced) and 14 patients had missing data related to study variables. The resulting 618 cases provide the basis for the logistic regression analyses reported below. Variables listed in Table I were analyzed for association with dropout; 3 of the variables had a substantial proportion of missing values (cholesterol 41%, triglycerides 41%, ponderal index [height/weight$^{1/3}$] 39%) and for these variables the mean value computed over all cases was substituted for missing values.[9] The appropriateness of this procedure is discussed later.

**Exercise regimens:** The training regimens are described elsewhere.[6,8] The high intensity exercise group carried out supervised endurance exercise at between 65 and 85% of estimated maximal oxygen uptake; subjects were asked to

* The number of subjects given at the top of the column applies to all variables except 2, 3, and 4. For these variables the sample size for dropouts and compliers in analysis A is 122 and 195, respectively, and in analysis B is 112 and 165. † Differences between dropouts and compliers were significant; see Table II for detailed analysis. ‡ Resting. § >1 h/wk. ‖ Cough or sputum (sometimes or often). ¶ Rosenman/ Friedman Type A or B. MI = myocardial infarction.

supplement the twice weekly supervised sessions by carrying out homework on their own at least 4 other times/week. The light intensity exercise group met once a week for progressive relaxation and supervised recreation activities structured to produce minimal training. All supervised sessions were attended by a physician and cardiopulmonary resuscitation equipment was immediately available.

**Determination of dropout:** Individuals missing 8 consecutive supervised activity sessions were considered dropouts. Reasons for dropout were categorized as follows: transition (change of job or domicile), inconvenience (time of day or too busy), psychosocial factors (lack of motivation or interest), medical problems (such as increasing angina, arthritis, and alcoholism), miscellaneous, and unknown. Subjects who died from causes other than myocardial infarction or who had coronary bypass surgery were not considered dropouts. The classification of subjects who left the trial because of reinfarction is discussed later.

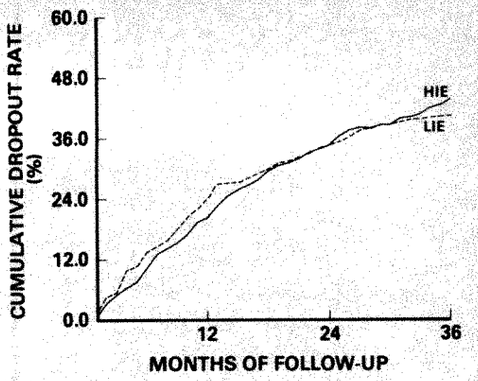

**FIGURE 1.** Month-by-month life-table cumulative dropout in the 678 subjects who were stratified and randomly allocated to the high intensity exercise group (HIE; n = 351) and to the low intensity exercise group (LIE; n = 327) and who were traced for reinfarction status at the end of the study.

**Statistical analysis:** Of the 618 subjects eligible for the multivariate analyses, 270 were classified as dropouts, of whom 26 subsequently had a reinfarction during the 3-year observation period. Among the 348 compliers, 53 left the trial due to a reinfarction during the 3-year period. In order to reduce the potential bias arising from factors related both to reinfarction and to dropout, 2 approaches were taken in the comparison of dropouts and compliers.

The first approach assumed that subjects whose reinfarction occurred while they were complying with the program were "forced" dropouts and were considered compliers. Thus in this analysis, the 270 dropouts were compared with the remaining 348 subjects, including among the latter those who had reinfarction while in the study.

The second approach assumed that subjects withdrawing because of reinfarction should not be considered compliers for, had the infarction not occurred, they might have subsequently dropped out. After considering the various types of association that could occur among predictor variables and the risk of reinfarction we concluded that the potential bias of the first analysis would be reduced most by excluding all reinfarctions. Therefore, in this analysis 244 dropouts were compared with 295 compliers.

For each of these 2 approaches, a stepwise multiple linear logistic regression[9] was performed with 3-year dropout status as the dependent variable, and the 14 risk factors listed in Table I as explanatory variables. The following comparisons were made: (A) dropouts versus compliers (ignoring reinfarction status among compliers), and (B) dropouts versus compliers (excluding all subjects with reinfarction). This type of analysis allows the effect of a given variable to be calculated independently of any other variable with which it may or may not be associated.

Likelihood ratio tests were used in each analysis to determine which variables were statistically significant ($p < 0.05$) independent predictors of dropout. Standardized coefficients and 95% confidence intervals for the adjusted relative odds of dropout were calculated for each of these variables.[9]

## Results

Descriptive statistics for the 14 variables used in the prediction of dropout are listed in Table I. There was no difference in dropout rate between the 2 exercise intensity groups (Fig. 1). There was a considerable

difference in dropout among the participating centers, ranging from 67.2 to 37.4%, with an overall dropout rate of 46.5% (n = 315).

Transition was given as the reason for dropout by 24.8%, psychosocial reasons by 39.7%, medical reasons by 15.9%, and inconvenience by 5.7%; miscellaneous reasons were given by 12.1%, and the reason for dropout was unknown for 1.9%.

**Multivariate analysis of 3-year dropout status:** *(A) Dropouts and compliers, ignoring reinfarction among compliers (n = 618):* Stepwise logistic regression showed that the proportion of smokers, blue collar workers, and subjects with cough and sputum was significantly greater in dropouts than compliers; dropouts were also significantly younger than compliers, and had higher resting systolic blood pressure (Table I, Fig. 2). Smokers were 2.46 times more likely to be dropouts than nonsmokers, blue collar workers 1.66 times as likely as white collar workers to be dropouts, and subjects with cough and sputum 1.60 times more likely to be dropouts than those without cough and sputum (Table II). The results for resting systolic blood pressure imply that an increase of 10 mm Hg is associated with an estimated relative odds for dropout of 1.13; similarly, an increase of 10 years in age is associated with a reduction in relative odds for dropout to 0.72 (Table II). These results assume an additive model in which the effect of a given variable on dropout status is the same for all values of the other variables. However, although this model might be appropriate as a first approximation, we also examined the interactions among the 5 main variables associated with dropout (smoking, blue collar occupation, presence of cough, younger age, and higher systolic blood pressure). When the 10 pairwise interaction terms among these 5 variables were added in a stepwise fashion, a significant interaction term ($p < 0.05$) was found only between age and cough and sputum, indicating that the positive relation between dropout status and cough and sputum was strongest for older men.

*(B) Dropouts and compliers, excluding all reinfarction (n = 539):* All 5 variables found to be independent risk factors for dropout status in analysis A were also statistically significant risk factors in analysis B; in addition, subjects with a history of angina were more likely to be dropouts than those without angina (Table I). Standardized coefficients, adjusted relative odds, and confidence intervals are detailed in Table II. An exploration of interactions among these 6 variables was performed in a manner similar to that for analysis A. The results showed that the interaction between age and cough and sputum remained statistically significant; in addition, the interaction between angina and systolic blood pressure was statistically significant ($p < 0.01$). The positive relation between dropout status and angina was strongest for subjects with relatively high levels of systolic blood pressure.

Finally, since the mean substitution method of handling missing data in these analyses may have diluted the statistical significance of changes in cholesterol, triglycerides, and ponderal index, the analyses were repeated for the subset of 317 subjects who had measured values for all 14 baseline variables. Cholesterol, triglyceride, and ponderal index remained nonsignificant in these analyses.

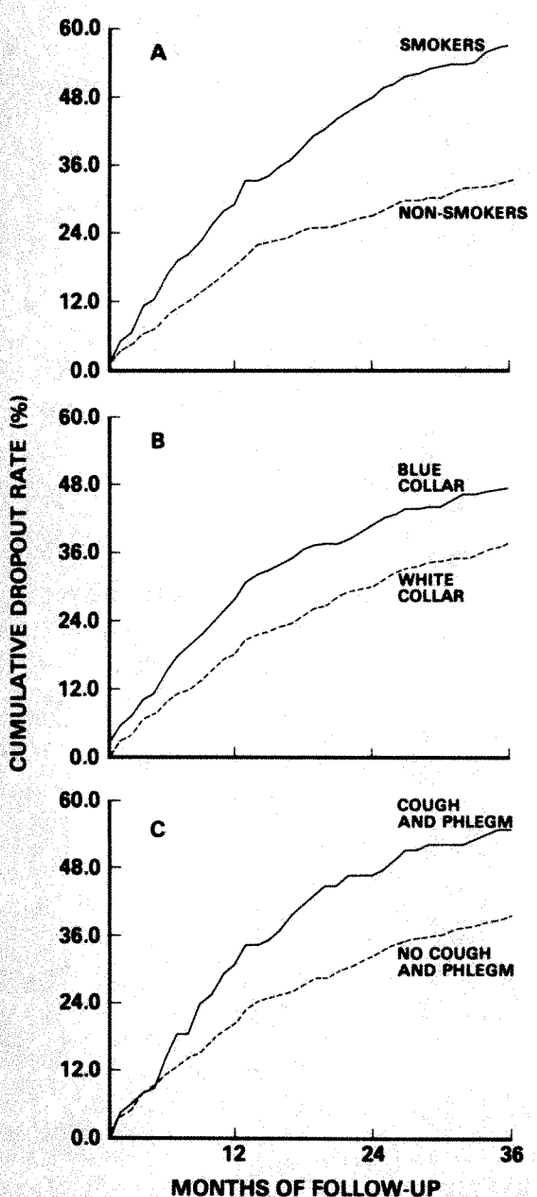

**FIGURE 2.** Month-by-month life-table cumulative dropout rate in the 618 subjects eligible for statistical analysis: **A,** in smokers and nonsmokers; **B,** in blue and white collar workers; and **C,** in subjects with and without cough and phlegm.

## Discussion

The OEHCS provided an opportunity to prospectively investigate dropout from 2 different supervised programs of physical activity after myocardial infarction. There was no difference in dropout between the 2 groups (high or low intensity exercise), suggesting that subjects tended to equally accept either high intensity exercise or what was essentially a "social encounter." Dropout may not be influenced by the prescribed activity itself but rather by other factors such as lack of

spouse support, inconvenience, or program factors such as uninterested staff.[10] Previous trials[3–5] have demonstrated no significant difference in reduction of recurrent myocardial infarction between exercising or control subjects, perhaps because of an insufficient study population.[5] As the OEHCS reported similar recurrence rates in the high and low intensity groups,[6] the equal acceptance of endurance training and relaxation-recreation programming seen in this trial has important rehabilitation implications. There is evidence that the supportive aspects of group interaction, whether emotional, social, educational, or some other known or unknown factors, together with modification of coronary-prone behavior, including an increase in exercise habits, are important in minimizing the incidence and severity of complication after myocardial infarction.[11] Thus, the long-term behavioral benefits from such rehabilitation programs focusing on exercise may be more important than physiologic changes, such as in maximal oxygen consumption.

The overall 3-year dropout rate was 46.5%, a figure considerably lower than that reported at 3 years in the Swedish[3] or at 1 year in the Finnish[4] trials, but considerably higher than that reported in the 3-year National Exercise Heart Disease Program (NEHDP).[5] However, the NEHDP had a built-in "preliminary pre-randomization program of low level exercise of 6 weeks duration that was designed to identify and exclude likely nonadherers to the planned exercise program . . ." [5]; if the OEHCS early dropouts (≤3 months) are allowed for, the subsequent rate was similar to the NEHDP. The greatest rate of dropout in the OEHCS occurred within the first 6 months of the trial; the dropout rate decreased thereafter (Fig. 1), supporting observations of a decreasing dropout over time previously made by ourselves[7,12] and other investigators in rehabilitation programs,[3,13,14] in preventive exercise programs[15] and in health care programs in general.[16] As suggested by Andrew et al,[10] 1 of the factors which can easily be instituted to reduce early dropout is a regular continued education program for the staff members and the continued involvement of the spouse in certain aspects of the program. The reasons for dropout in the OEHCS are similar to those previously reported in considerably more detail.[10]

Because recurrent myocardial infarction compounded the problem of defining a dropout, we took 2 different approaches to the classification of dropouts in the analysis of the data. In both analyses the importance of smoking and occupational status in predicting the potential dropout corroborates earlier observations made in a smaller sample from the OEHCS.[7,12] As there was no interaction between smoking and occupational status, the relative odds for these 2 variables may be multiplied to show that the estimated odds for dropout are more than 4 times higher for blue collar smokers than for white collar nonsmokers. In addition, younger age, higher resting systolic blood pressure, and presence of cough and sputum on entry were also consistently associated with dropout. One factor, angina, was significantly associated with dropout only when myocardial infarction was excluded (Table II). In analysis A (myocardial infarction status ignored) patients reinfarcting while in the study were classified as compliers. Clearly this classification might obscure any true relation of angina to volitional dropout, because angina is frequently associated with a poor postinfarction prognosis.[17] In analysis B (reinfarctions excluded), this bias did not pertain and angina was significantly associated with dropout. This is not surprising, since most patients with angina have symptoms during exercise. While it may be difficult to predict individual response, these data suggest that subgroups with a high likelihood of dropout can be identified.

Continued smoking after an infarction is an indicator of poor compliance with health behavior change and is associated with dropout from exercise studies,[7,12,13,18] although this has not been an invariable finding.[19] With regard to occupation, blue collar workers may have a poorer understanding both of the disease and the rehabilitation process than white collar workers[20] and they often have a greater anxiety level, possibly because of concern about their ability to continue working.[21] Moreover, if the blue collar worker perceives the exercise intensity to be lower than in his daily work, he may be likely to question the need for the extra, "unneces-

sary" exercise. Blue collar workers comprised more than 40% of this study population and a significant proportion dropped out of the OEHCS.[7,12] This has not been reported in other rehabilitation programs, perhaps because white collar workers make up the majority of other study populations.[22,23] The presence of cough or sputum as a predictor of dropout is somewhat more difficult to explain but it is possible that exercise makes this symptom worse and thus leads to a greater rate of withdrawal from the program in older men bothered by coughing on entering the study. Although it showed an effect which was independent of current smoking, this symptom may indicate past smoking habits in patients who gave up smoking at the time of their infarction.

We have identified a number of characteristics that distinguish dropouts from compliers. The more important appear to be smoking, blue collar occupation, and angina. It may be difficult to generalize from results observed in a randomized trial to nonexperimental exercise programs having different motivational and programmatic features. However, the factors reported here should not only be given consideration when referring patients to an exercise rehabilitation program but also need to be kept in mind when studies to improve compliance are being designed.

# Ventricular Electrical Instability: A Predictor of Death After Myocardial Infarction

DAVID A. RICHARDS, FRACP, DAVID V. CODY, FRACP, ALAN R. DENNISS, MB, PAUL A. RUSSELL, FRACP, ALAN A. YOUNG, FRACP, and JOHN B. UTHER, FRACP

**The results of a prospective study of ventricular electrical instability after myocardial infarction (MI) are presented. Ventricular electrical stability was assessed using a standardized protocol of programmed stimulation in 165 hemodynamically stable patients 6 to 28 days after acute MI. Ventricular electrical instability was defined as induction at programmed stimulation of ventricular fibrillation (VF) or ventricular tachycardia (VT) lasting at least 10 seconds. Of 165 MI survivors, 38 (23%) had ventricular electrical instability. No significant differences were noted between stable and unstable patients in terms of coronary prognostic index, elevation of serum creatine phosphokinase, coronary anatomy, site of MI, or frequency of VT within 48 hours of MI. The mean follow-up period was 8 months (range 0 to 12).**

**There were 7 deaths in stable patients (5 from cardiogenic shock, 1 from septicemia, and 1 unwitnessed) and 10 deaths in unstable patients (8 instantaneous, 1 from cardiogenic shock, and 1 unwitnessed) during the subsequent year. In addition, 2 of 127 stable patients and 4 of 38 unstable patients had spontaneous VT from which they were satisfactorily resuscitated. Thus, the sensitivity of ventricular electrical instability as a predictor of instantaneous death or spontaneous VT was 86% and the specificity 83%. The predictive accuracy of the absence of ventricular electrical instability as an indicator for the absence of instantaneous death or spontaneous VT was 98%. The predictive accuracy of the presence of ventricular electrical instability as a predictor of instantaneous death or spontaneous VT was 32%.**

**Thus, patients with ventricular electrical instability after MI have a high risk of instantaneous death within 1 year; patients without ventricular electrical instability after MI have a low risk of instantaneous death within 1 year; prospective studies of antiarrhythmic therapy and measures to prevent reinfarction and optimize left ventricular performance are required to determine whether instantaneous death can be prevented in unstable patients; and therapy to prevent reinfarction and optimize left ventricular performance may offer the best chance to improve prognosis in stable patients.**

The overall probability of death after acute myocardial infarction (MI) is related to age, presence of previous MI, and left ventricular dysfunction.[1–4] However, approximately half of all deaths during the year after MI are sudden,[1,3–12] are due to ventricular fibrillation (VF) or ventricular tachycardia (VT),[13] and are not necessarily associated with clinical evidence of acute myocardial ischemia or postmortem evidence of reinfarction.[14]

Greene et al[15] in 1978 reported that repetitive ventricular beats (1 nonstimulated ventricular beat after programmed stimulation with a single ventricular extrastimulus introduced during atrial drive) indicated ventricular electrical instability[15] and predicted VT and sudden death after MI.[10] However, the clinical significance of repetitive ventricular beats has since been questioned by several investigators,[16–18] and controversy remains regarding the predictive value of programmed stimulation after MI.[19] This report presents a new protocol of programmed stimulation and a new definition of ventricular electrical instability. The aim of this study was to ascertain the value of ventricular electrical instability as a predictor of death after MI.

## Methods

Ventricular electrical stability was assessed by programmed stimulation in 165 patients 6 to 28 days (mean 10) after acute MI. These patients comprised a subgroup of 341 consecutive patients admitted to Westmead Hospital with acute MI between March 1980 and May 1981. Of the original 341 patients, 37 died within 5 days of admission. Ventricular electrical

stability was not assessed in 139 (nonassessed patients) of the remaining 304 patients, because consent for study was either refused or not requested (because of persistent ischemia, uncontrolled cardiac failure, or cardioactive medication).

Written informed consent was obtained and the administration of all cardioactive medications ceased at least 5 days before study. Patients were postabsorptive but not sedated. Quadripolar electrode catheters were introduced into the right ventricle through femoral venipunctures. Drive trains of 8 stimuli followed by single and paired extrastimuli at twice diastolic threshold and 20 mA (rectangular pulses 2 ms in duration from a Medtronic 5325 programmable stimulator) were applied at the right ventricular apex and outflow tract. The drive cycle length ($S_1$-$S_1$) was set as long as possible, usually about 600 ms (only 1 drive cycle length was tested), and single extrastimuli ($S_2$) were introduced during diastole from 300 ms in 10 ms decrements to the ventricular effective refractory period (ERP). With paired extrastimuli, $S_1$-$S_2$ was set at ERP plus 10 ms and the second extrastimulus ($S_3$) was introduced during diastole from 300 ms in 10 ms decrements to ventricular refractoriness. This sequence was applied first at the right ventricular apex and then at the right ventricular outflow tract in each case at twice diastolic threshold. The entire sequence was then repeated at 20 mA. The protocol was terminated prematurely if VF or VT lasting more than 10 seconds occurred. Such patients were classified as unstable (ventricular electrical instability). All of these were converted promptly to sinus rhythm without neurologic or other sequelae. The remaining patients were classified as stable (ventricular electrical stability).

Ventricular electrical stability (or instability) was noted but not used to influence subsequent management. However, if a patient exhibited spontaneous VT or VF, antiarrhythmic therapy was introduced. Other data recorded before hospital discharge included a Norris Coronary Prognostic Index[1] (CPI) and a maximal serum level of creatine phosphokinase (CK). Left ventricular ejection fractions[20] were calculated from right anterior oblique cineventriculograms in 82 of 100 patients who underwent ventriculography (ejection fractions were not calculated in 18 patients with ventricular aneurysms). The presence of a ventricular aneurysm was noted if paradoxical systolic wall motion was observed in the right anterior oblique cineventriculogram. Coronary arteries were reported as significantly diseased when there was a >50% reduction in the luminal diameter of the left main coronary artery or a >75% reduction in luminal diameter in any of the other major coronary arteries. Angiography was not performed routinely in all postinfarct patients, and indications for angiography were not the same in all cases.

Patients were followed for up to 12 months (mean 8) and survival rates were determined by the life table method.[21,22]

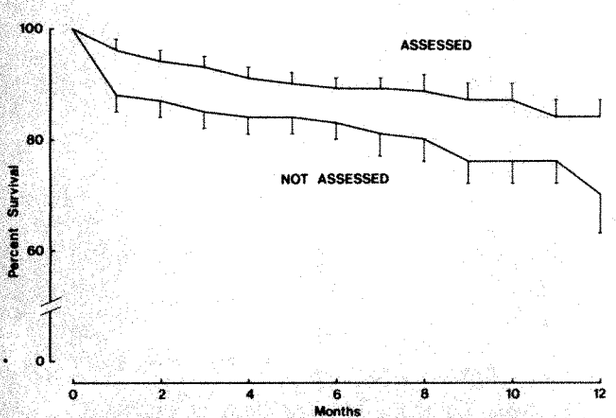

**FIGURE 1.** Actuarial survival curves for assessed and nonassessed patients. **Bars** indicate 1 standard error of the mean for estimation of survival rates at each month.

## Results

Clinical profiles of assessed and nonassessed patients before hospital discharge are summarized in Table I. The assessed group consisted of more male patients, more patients with transmural infarction (appearance of new Q waves on the 12-lead electrocardiogram), and fewer patients with anterior infarctions than did the nonassessed group. The mean age and CPI[1] were higher in nonassessed patients, reflecting exclusion from study of some older patients and those with uncontrolled cardiac failure. No significant differences were noted in the incidence of VF or VT within 48 hours of admission (no patients had exhibited spontaneous VF or VT between the 48 hours after infarction and programmed stimulation), in the maximal recorded value of CK, in coronary anatomy, or in the incidence of ventricular aneurysm. Ejection fractions were similar in assessed and nonassessed patients. The results of life table analysis of 1-year survival of assessed and nonassessed patients are illustrated in Figure 1.

**TABLE II Clinical Profiles of Stable and Unstable Patients**

* Values given are mean ± standard error of the mean. NS = not significant.

The relatively low first-month survival rate among nonassessed patients (log-rank test,[22] $p < 0.01$) occurred because of exclusion from assessment of patients with uncontrolled cardiac failure or persistent ischemia. Survival rates for individual months 2 through 12 were not significantly different. The cumulative 1-year survival rates for assessed and nonassessed patients were 84 and 70%, respectively. The majority of deaths in nonassessed patients (16 of 28) were due to cardiogenic shock, 4 were virtually instantaneous with no evidence of acute ischemia or cardiac failure, 4 were noncardiac, and 4 were unwitnessed. There were 17 deaths in the assessed patients: 8 were instantaneous, 6 were from cardiogenic shock, 1 was noncardiac, and 2 were unwitnessed.

Assessed patients were classified unstable or stable according to whether or not VF or VT (lasting at least 10 seconds) was induced at programmed stimulation. The clinical profiles of stable and unstable patients are summarized in Table II.

The incidence of transmural infarction was higher (unstable 89%, stable 71%) and ejection fractions (unstable 0.47, stable 0.58), when measured, tended to be lower among unstable patients (range of ejection fractions: unstable patients, 0.17 to 0.66; stable patients, 0.21 to 0.66), but the groups were similar in all other respects. The life table analysis of 1-year survival of stable and unstable patients is illustrated in Figure 2.

Although the cumulative 1-year survival rate for stable patients was 91%, it was only 65% for unstable patients ($p < 0.001$). There were significant differences also in survival rates for individual months 4 ($p < 0.01$) and 5, 6, and 9 ($p < 0.05$).

The clinical profiles of stable and unstable survivors and nonsurvivors are compared in Table III. There were

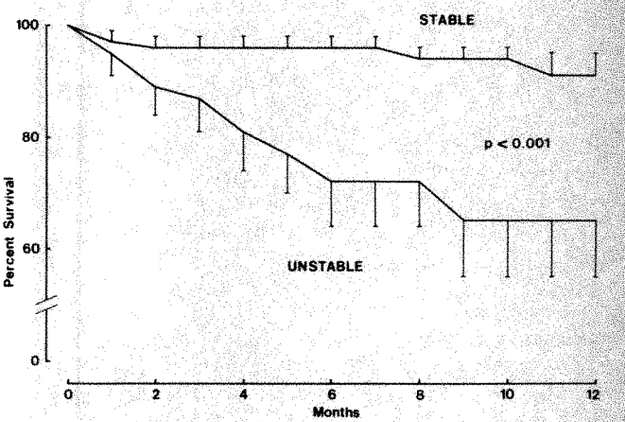

**FIGURE 2.** Actuarial survival curves for stable and unstable patients. **Bars** indicate 1 standard error of the mean for estimation of survival rates at each month.

**TABLE III Clinical Profiles of Survivors and Nonsurvivors**

| | Stable | | Unstable | |
|---|---|---|---|---|
| | Alive (n = 120) | Dead (n = 7) | Alive (n = 28) | Dead (n = 10) |
| Age (yr | 54 ± 1 | 59 ± 4 | 52 ± 2 | 61 ± 3 |
| Maximal CK (IU/liter) | 1,546 ± 104 | 1,628 ± 373 | 2,108 ± 277 | 1,653 ± 287 |
| CPI | 3.7 ± 0.2 | 5.3 ± 1.2 | 3.6 ± 0.6 | 6.7 ± 0.9 |
| VF or VT in 48 hours (%) | 15 | 29 | 14 | 20 |
| Transmural infarction (%) | 70 | 86 | 89 | 90 |
| Anterior infarction (%) | 46 | 29 | 32 | 60 |
| Diseased vessels (n) | 1.5 ± 0.1 (n = 56) | 2.0 (n = 1) | 1.6 ± 0.2 (n = 19) | 2.5 ± 0.5 (n = 2) |
| Ventricular aneurysm (%) | 11/56 | 0/1 | 3/19 | 1/2 |
| Ejection fraction | 0.59 ± 0.02 (n = 45) | 0.55 (n = 1) | 0.47 ± 0.03 (n = 16) | 0.37 (n = 1) |

significant differences between unstable survivors and nonsurvivors in terms of age ($p < 0.02$) and coronary prognostic index ($p < 0.01$). However, the range of the CPI among unstable nonsurvivors was wide (1.0 to 9.7). Of the 10 nonsurvivors, 7 had CPI <9. There was a higher incidence of death among unstable patients than among stable patients with transmural ($p < 0.01$) and anterior ($p < 0.001$) infarcts. These differences did not apply between stable and unstable patients with nontransmural or inferior infarcts. The mean ejection fraction for unstable survivors (n = 16) was less than that for stable (n = 45) survivors ($p < 0.01$). During the year no stable patient with ventricular aneurysm and only 1 unstable patient with a ventricular aneurysm died.

At the final review (or death), 20% of assessed patients were taking regular beta-adrenoceptor blocking drugs, 8% were receiving some other regular antiarrhythmic therapy, and 13% had undergone coronary artery bypass grafting (Table IV). There was no significant difference in survival of patients with or without medical or surgical therapy. The predictive value of ventricular electrical instability after myocardial infarction is indicated in Table V.

Death occurred in 7 stable patients; 5 died in cardiogenic shock, 1 patient had septicemia, and 1 death was unwitnessed. There were 10 deaths in unstable patients; 8 died virtually instantaneously without evidence of acute ischemia or cardiac failure (VF was documented in 5 of these patients during unsuccessful resuscitation), 1 patient died in cardiogenic shock after coronary artery bypass, and 1 death was unwitnessed. Thus, the sensitivity of ventricular electrical instability as a predictor of death after infarction was 59% and the specificity was 81%. The predictive accuracy of ventricular electrical stability, that is, the absence of instability, as a predictor of survival was 94% and the predictive accuracy of ventricular electrical instability, that is, the presence of instability, as a predictor of death was 26%. Because there were no instantaneous deaths among stable patients, the sensitivity of ventricular electrical instability as a predictor of instantaneous death was 100%. The predictive accuracy of ventricular electrical stability (absence of instability as an indicator for the absence of subsequent instantaneous death) was also 100%. The specificity of ventricular electrical instability as a predictor of instantaneous death was 81% and the predictive accuracy was 21%.

During the year 4 of 38 unstable patients exhibited spontaneous VT, in the absence of further acute ischemia. In contrast, only 2 of 127 stable patients exhibited spontaneous VT. In 1 patient a ventricular aneurysm had developed after reinfarction, and the patient was subsequently unstable in the laboratory when restudied. The other patient was asymptomatic, with an idioventricular rhythm that caused no hemodynamic embarrassment. Thus, the sensitivity of ventricular electrical instability as a predictor of instantaneous death or spontaneous VT was 86% and the specificity was 83%. The predictive accuracy of ventricular electrical stability was 98% and of instability 32%.

## Discussion

The major finding of this study is that although patients with ventricular electrical instability after myocardial infarction have a high risk of death from spontaneous VF, patients without ventricular electrical instability have a very low risk of death from spontaneous VF. Of unstable patient deaths, 80% (8 of 10) were instantaneous and VF was documented in 5 of these. A further 11% of unstable patients (4 of 38) were resuscitated from spontaneous VT during the year. In contrast,

**TABLE IV Therapy in Stable and Unstable Patients**

| | Stable | | Unstable | | |
|---|---|---|---|---|---|
| | Alive (n = 120) | Dead (n = 7) | Alive (n = 28) | Dead (n = 10) | p |
| BB (20%) | 27 | 0 | 6 | 0 | NS |
| AA (8%) | 6 | 0 | 5 | 2 | NS |
| CABG (13%) | 18 | 0 | 3 | 1 | NS |

AA = medical antiarrhythmic therapy other than beta-adrenoceptor blockade; BB = beta-adrenoceptor blockade; CABG = coronary artery bypass graft.

**TABLE V Value of Programmed Stimulation As a Predictor of Death, Instantaneous Death, and Spontaneous VT**

| | | | Predictive Accuracy of | |
|---|---|---|---|---|
| | Sensitivity | Specificity | Stability | Instability |
| All deaths (%) | 59 | 81 | 94 | 26 |
| Instantaneous deaths (%) | 100 | 81 | 100 | 21 |
| Instantaneous death or spontaneous VT (%) | 86 | 83 | 98 | 32 |

Sensitivity = number of events predicted by ventricular electrical instability (true-positives)/true-positives + number of events falsely predicted by ventricular electrical stability (false-negatives); specificity = number of events predicted by ventricular electrical stability (true-negatives)/true-negatives + number of events falsely predicted by ventricular electrical instability (false-positives); predictive accuracy of stability = true-negatives/true-negatives + false-negatives; predictive accuracy of instability = true-positives/true-positives + false-positives.

none of the deaths in stable patients were instantaneous and in only 2% did spontaneous VT develop (1 patient had VT after reinfarction and development of a left ventricular aneurysm, and 1 patient had an asymptomatic idioventricular rhythm without hemodynamic embarrassment). It remains to be determined whether therapeutic intervention of any kind improves prognosis in unstable patients. A prospective randomized study of antiarrhythmic therapy in unstable patients is being conducted at an institution as a first step toward answering this question.

The problems for patients without ventricular electrical instability appear to be different. Because most deaths among stable patients were due to cardiogenic shock (5 of 7), therapy aimed at preventing reinfarction and optimizing left ventricular performance may offer the best chance to improve prognosis in these patients.

The only significant differences between stable and unstable patients before hospital discharge occurred in the incidence of transmural infarction (71% stable, 89% unstable) and the mean ejection fraction (0.58 stable, 0.47 unstable). Notwithstanding these differences, most assessed patients had survived transmural MI and none had severely depressed left ventricular function. Ventricular electrical stability was assessed in the absence of acute ischemia[23] 6 to 28 days after MI. In contrast to previous reports,[10,16,18] we defined ventricular electrical instability as VF or VT lasting at least 10 seconds. This definition was chosen because of controversy[19] concerning the clinical significance of repetitive ventricular beats[10] (1 or a few nonstimulated beats) after programmed stimulation.

Our standardized protocol of programmed stimulation was developed to provide a simple and rapid means of assessing ventricular electrical stability. Left ventricular stimulation was not included because of the additional potential complications and additional time required for study. The 2 right ventricular stimulation sites were chosen because catheter manipulation could be readily achieved using anteroposterior X-ray control only. Stimulation with 20 mA (the maximal output of the Medtronic 5325 stimulator) as well as twice diastolic current threshold stimulation, may have resulted in some false-positive results. However, omission of 20 mA stimulation would have resulted in some false-negative results (3 unstable patients who died instantaneously and 1 patient who had spontaneous VT had exhibited ventricular electrical instability at 20 mA only). The optimal current intensity for stimulation for demonstrating ventricular electrical instability has not been defined.

Nevertheless, the predictive value of the present protocol is clear. The absence of ventricular electrical instability was associated with a high probability of survival for 1 year (91%, Fig. 2), whereas its presence was associated with a significantly ($p < 0.001$) lower probability of survival (65%, Fig. 2).

Schulze et al,[4] studying 81 survivors of acute MI during a 10-month period, found that patients with an ejection fraction (biplane radionuclide) <40% had a higher incidence of sudden death (8 of 45, 18%) than did patients with an ejection fraction ≥40% (0 of 36). These investigators found complicated ventricular arrhythmias (modified Lown class: III, multifocal ventricular premature contractions [VPC]; IV, coupled or bigeminal VPC; and V, VT or R on T VPC) during continuous 24 hour Holter monitoring in 3 patients with an ejection fraction ≥40% and in 26 with an ejection fraction <40%. Complicated ventricular arrhythmias were present in all patients who died suddenly. No patient without complex arrhythmia (modified Lown class: 0, no VPC; I, unifocal PVC <30/h in all hours; and II, unifocal PVC >30/h in any hour) died. Sudden death occurred in 8 of 29 patients (28%) with complicated ventricular arrhythmias. All 8 patients who died suddenly were in the subgroup of 26 patients with an ejection fraction <40% and complicated arrhythmias. These data are similar to those of Bigger et al,[24] who studied 430 MI survivors and observed sudden death in 11 of 50 (22%), with VT (≥3 consecutive ventricular complexes) on Holter monitoring. However, 75% of patients who died suddenly had not exhibited VT and their death would not have been predicted by Holter monitoring.

The data of Bigger et al[24] show that VT on Holter monitoring is not a necessary or sufficient condition to predict death or sudden death. The data of Schulze et al[4] imply that complicated VPC on Holter monitoring and an ejection fraction less than 40% are necessary conditions for predicting sudden death. However, these investigators showed that low ejection fraction is not a sufficient condition to predict death or sudden death. Our own data appear to indicate that ventricular electrical instability is probably a necessary but not sufficient condition for predicting sudden death.

The subsets of patients at high risk for sudden death in the aforementioned series[4,24] and our own must, to some extent, overlap. In the future it may be possible to use a combination of noninvasive and invasive tests to identify more specifically the subset of MI survivors at highest risk for sudden death.

Sudden death from spontaneous VT or VF during the first year after MI requires the presence of at least 2 conditions: (1) A ventricular substrate that can sustain VT or VF in the absence of acute myocardial ischemia. Intraventricular reentrant circuits could provide this substrate. (2) Some perturbation to initiate VT or VF. Such perturbations may include spontaneous VPC or spontaneous changes in conduction velocities or refractory periods within reentrant circuits.

Probably a critical mass of infarct is required to have within it or around it potential reentrant circuits. Hearts with larger infarcts may be more likely to incorporate intraventricular reentrant circuits than hearts with small infarcts. Hence, it is not surprising that left ventricular dysfunction (low ejection fraction) and complicated ventricular arrhythmias on Holter monitoring are associated with spontaneous VT, VF, and sudden death in many but not all cases.

The crucial determinant of predisposition to VT or VF (and sudden death) is the capacity to sustain VT or VF in the presence of spontaneous VPC. Ventricular electrical instability as described herein may be that determinant.

We conclude that (1) patients with ventricular electrical instability after myocardial infarction have a high risk of sudden death within 1 year; (2) patients without ventricular electrical instability after myocardial infarction have a very low risk of sudden death within 1 year; (3) prospective studies (of antiarrhythmic therapy and measures to prevent reinfarction and optimize left ventricular performance) are required to determine whether sudden death can be prevented in unstable patients; (4) therapy to prevent reinfarction and optimize left ventricular performance may offer the best chance to improve prognosis in stable patients.

# Status of the Major Epicardial Coronary Arteries 80 to 150 Days After Percutaneous Transluminal Coronary Angioplasty

## Analysis of 3 Necropsy Patients

BRUCE F. WALLER, MD, BRUCE M. McMANUS, MD, PhD, H. JOEL GORFINKEL, MD, JOAN C. KISHEL, MD, EDWARD C. H. SCHMIDT, MD, KENNETH M. KENT, MD, and WILLIAM C. ROBERTS, MD

**Certain clinical and necropsy cardiac findings are described in 3 men who had percutaneous transluminal coronary angioplasty (PTCA) of the left anterior descending (LAD) coronary artery 80, 90, and 150 days before sudden death. Each patient had a decrease in the mean transstenotic coronary gradient (17, 38, and 43 mm Hg) and an angiographic increase in the LAD luminal diameter (55, 60, and 65%). At necropsy, the LAD coronary artery in the area of the PTCA in each patient was narrowed 76 to 95% in cross-sectional area by atherosclerotic plaques. No cracks in plaques or other lesions which may have resulted from the PTCA procedure were identified histologically in the LAD coronary artery of any patient.**

Several studies have described morphologic changes early (≤60 days) in coronary arteries in humans[1–3] and in animals[4–6] after PTCA. Although several reports[7–10] have described angiographic appearances of coronary arteries late (>60 days) after PTCA, morphologic observations have not been reported in coronary arteries subjected to PTCA >60 days before death. In this report, clinical and necropsy cardiac findings are described in 3 men who died suddenly 80, 90, and 150 days, respectively, after PTCA.

### Patients Studied

**Clinical observations:** Each patient had exertional angina pectoris for only 1 to 2 months before PTCA. Coronary angiography and PTCA performed 80, 90, and 150 days, respectively, before death disclosed severe (76 to 95% diameter reduction) luminal narrowing of the LAD coronary artery and insignificant (<50% diameter reduction) narrowing of the left main, left circumflex, and right coronary arteries (Table I, Fig. 1 to 3). At PTCA, the LAD in each patient was dilated 55, 60, and 65%, respectively (Table I), and the mean coronary pressure gradient fell 17, 38, and 43 mm Hg, respectively, in the 3 patients. Exercise treadmill testing in each patient 1 to 11 days after PTCA disclosed electrocardiographic changes of J point depression in 2 patients (Patients 2 and 3) and no changes in the third patient. No patient developed angina pectoris during or within an hour of the exercise test.

Angina pectoris did not recur after PTCA in Patients 1 and 2. Patient 3 remained pain-free for the first 105 days after PTCA, but during the last 45 days he had 3 episodes of mild exertional angina relieved promptly by nitroglycerin. After PTCA, all 3 patients thereafter received long-term administration of dipyridamole; 2 (Patients 1 and 2) received salicylates; 2 (Patients 2 and 3) received isosorbide dinitrate; and 1 patient each received verapamil (Patient 1) and nifedipine (Patient 2). Two patients (Patients 2 and 3) died suddenly at home or work without apparent chest pain. Patient 1 was killed during an automobile accident while intoxicated (alcohol).

**Morphologic observations:** At necropsy, no foci of myocardial fibrosis or necrosis were present. In all 3 patients, the 4 major epicardial coronary arteries were excised from the heart and cut transversely into 5-mm segments; a Movat-stained histologic section was prepared from each segment and examined. The results of the quantitative studies, representing the consensus of 3 observers (BFW, BMM, JCK), are summarized in Figure 4.

**TABLE I Observations in 3 Necropsy Men Who Died >60 Days After Percutaneous Transluminal Coronary Angioplasty (PTCA)**

| Observation | Patient 1 | 2 | 3 |
|---|---|---|---|
| Age (yr) at death | 33 | 48 | 57 |
| Systemic pressure (mm Hg) | 135/90 | 110/80 | 150/90 |
| Interval (days) from PTCA to death | 80 | 90 | 150 |
| Maximal coronary narrowing by angiography (% diameter reduction) | | | |
| LM | 0 | 0 | 0 |
| LAD | 80 | 85 | 85 |
| LC | ≤50 | ≤25 | ≤25 |
| R | ≤50 | 0 | ≤25 |
| Change (% diameter reduction) in LAD | 80 → 25 | 85 → 25 | 85 →20 |
| Mean intracoronary pressure (mm Hg) before → after dilation | | | |
| Proximal | 104 → 85 | . . . | 80 → 80 |
| Distal | 52 → 50 | . . . | 25 → 68 |
| Gradient | 52 → 35 | 50 → 12 | 55 → 12 |
| Maximal coronary narrowing at necropsy (% cross-sectional area) | | | |
| LM | 26–50 | 0–25 | 0–25 |
| LAD | 76–95 | 76–95 | 76–95 |
| LC | 76–95 | 26–50 | 51–75 |
| R | 76–95 | 76–95 | 51–75 |
| Cororary narrowing at necropsy at site of PTCA (% cross-sectional area) | 76–95 | 76–95 | 75–95 |
| Heart weight (g) | 450 | 490 | 415 |

LAD = left anterior descending; LC = left circumflex; LM = left main; R = right.

The site of the PTCA was determined from the area of maximal diameter reduction on the pre-PTCA coronary angiogram (Fig. 1). The catheter diameter just proximal to its tip was measured (in millimeters) on a black and white glossy print of 1 frame of the cineangiogram. A right anterior oblique angiographic view was used to view the bifurcation of the LAD and left circumflex coronary arteries. A magnification correction factor was determined by dividing the angiographic catheter diameter by the actual catheter diameter (provided by the manufacturer). The angiographic distance (in millimeters) from the origin of the LAD from the left main coronary artery to the site of maximal diameter reduction was measured. To locate this area of the LAD at necropsy, the distance measured on the angiogram was divided by the magnification correction factor. The LAD length was then measured at necropsy starting at the origin of the LAD from the left main coronary artery. The 5-mm coronary artery segment containing this area was recorded.

In each patient, at least 1 of the 4 major coronary arteries was narrowed 76 to 95% in cross-sectional area by atherosclerotic plaques: the LAD in all 3 patients, the right in Patients 1 and 2, and the left circumflex in Patient 1. The site of the PTCA in the LAD coronary artery in each patient was narrowed 76 to 95% in cross-sectional area by atherosclerotic plaque. The 5-mm segment of LAD containing the site of PTCA in each patient was serially sectioned at 10 $\mu$m intervals; every fifth section was stained. A total of 72 histologic sections in the area of PTCA was examined (26 in Patient 1, 34 in Patient 2, and 12 in Patient 3). Of the total 153 5-mm coronary segments from the 3 patients, none was narrowed 96 to 100%, 14 (9%) were narrowed 76 to 95%, and 34 (22%) were narrowed 51 to 75% in cross-sectional area by athero-

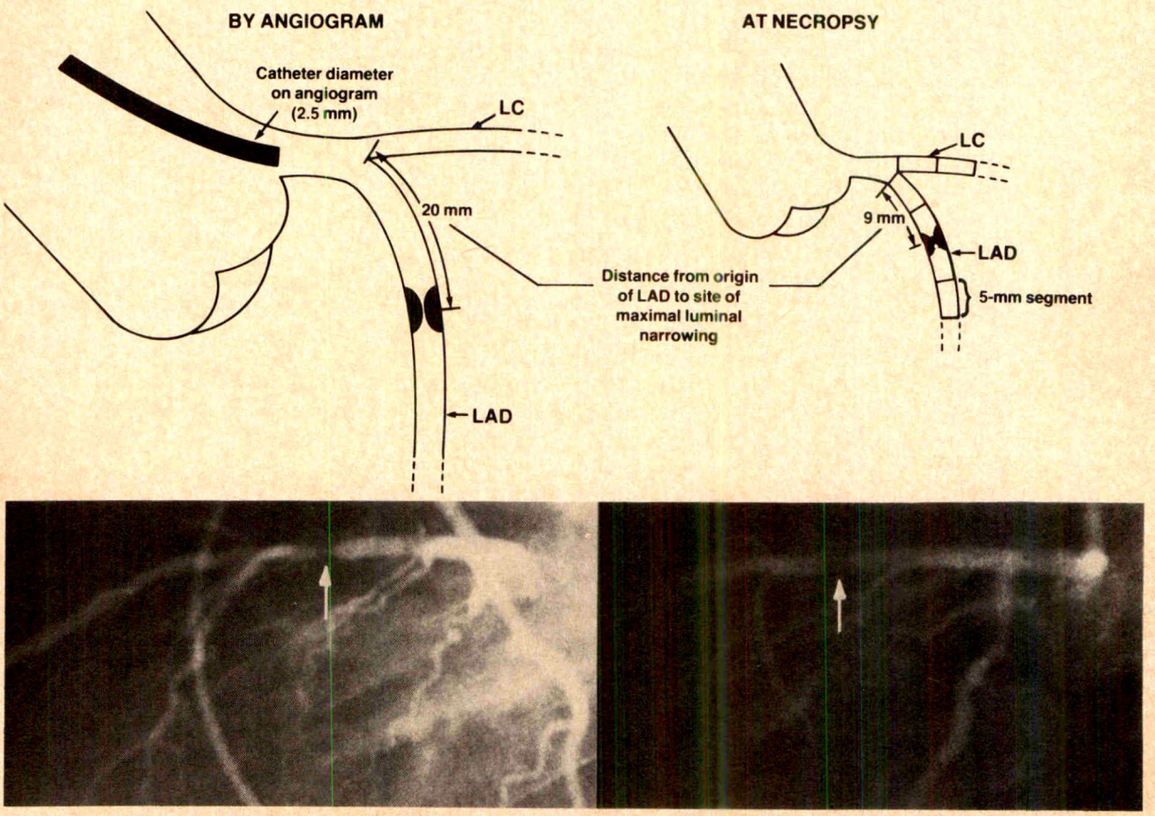

**FIGURE 1.** Patient 1. **Top panel,** diagram illustrating method of determining at necropsy the site of PTCA during life. **Bottom panels,** frames of coronary angiogram showing an increase in diameter of the left anterior descending (LAD) artery after PTCA (**arrows**). LC = left circumflex coronary artery.

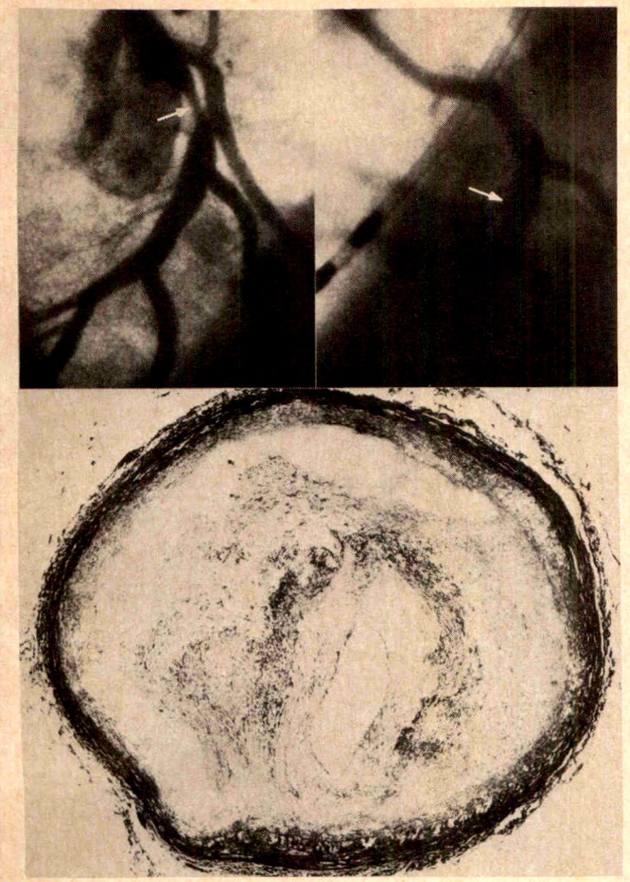

**FIGURE 2.** Patient 2. **Top panels,** frames of coronary angiogram 90 days before death showing an increase in diameter of the LAD artery after PTCA (**arrows**). **Bottom panel,** histologic section of the LAD artery at the site of previous PTCA procedure, showing severe luminal narrowing by atherosclerotic plaque (Movat stain; magnification ×22).

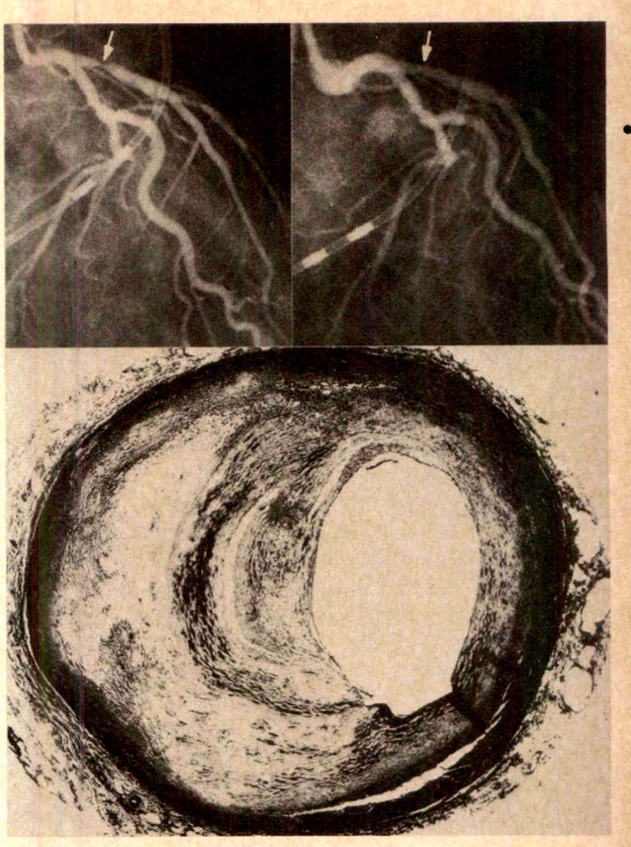

**FIGURE 3.** Patient 3. **Top panels,** frames of coronary angiogram 150 days before death showing an increase in diameter of the LAD artery after PTCA (**arrows**). **Bottom panel,** histologic section of the LAD artery at the site of a previous PTCA procedure, showing severe luminal narrowing by atherosclerotic plaque (Movat stain; magnification ×23).

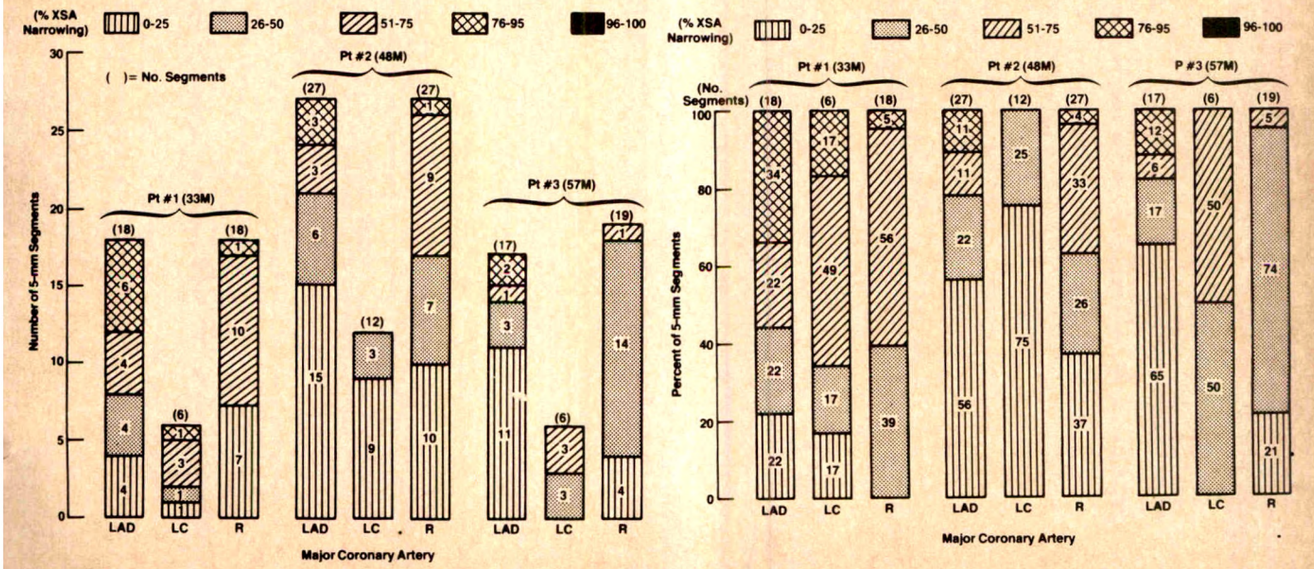

**FIGURE 4.** Number (**left panel**) and percent (**right panel**) of 5-mm segments of the LAD, left circumflex (LC), and right (R) coronary arteries narrowed to various degrees in cross-sectional area (XSA) by atherosclerotic plaques in the 3 necropsy patients.

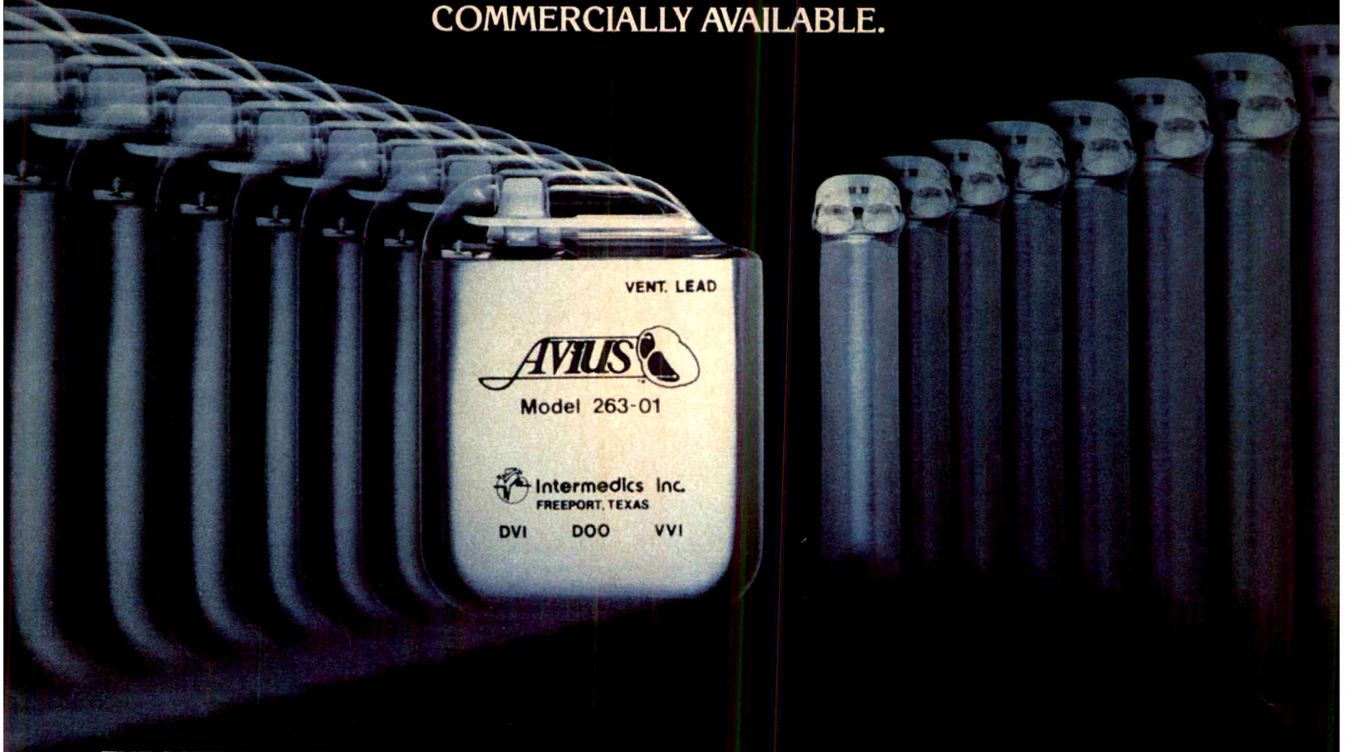
sclerotic plaques (Fig. 4). In each patient, the LAD coronary artery had the most segments narrowed 76 to 95%: 6 of 8 in Patient 1, 3 of 4 in Patient 2, and 2 of 2 in Patient 3. Histologic assessment of the atherosclerotic plaque in the area of the PTCA compared with other areas of atherosclerotic plaque in the same artery or other coronary arteries in the same patient disclosed no distinctive morphologic difference.

## Comments



The 3 men described above had PTCA of the LAD coronary artery 80, 90, and 150 days before death; each had a decrease in the mean transstenotic coronary gradient and an angiographic increase in the lumen of the LAD coronary artery. Only 1 had angina pectoris after the PTCA procedure, and each died suddenly. At necropsy, each patient had 76 to 95% cross-sectional area narrowing by atherosclerotic plaques in the area of the PTCA procedure. Despite examination of numerous sections of the coronary artery, histologic study of the atherosclerotic plaques in the area of the PTCA did not disclose any morphologic lesions attributable to the PTCA procedure. Indeed, comparison of the composition of the plaques at the site of the PTCA with plaques in other areas of the LAD and with those in the other major coronary arteries in the same patient did not disclose any distinctive differences. While splits, tears, and breaks have been described histologically in coronary arteries of humans and in animals immediately after the PTCA procedure,[1–6] these distinctive morphologic lesions were not recognized late in our 3 patients.

# WE'VE SAID IT ONCE AND WE'LL SAY IT AGAIN:

## AVIUS™ IS THE SMALLEST, LIGHTEST, MULTIPROGRAMMABLE A-V SEQUENTIAL PACEMAKER COMMERCIALLY AVAILABLE.

### THE DIFFERENCE IS COMMERCIAL AVAILABILITY.

There's a lot of talk about new, small, A-V sequential pacemakers. But at 68 grams and 11mm thin, AVIUS is still the smallest, lightest, multiprogrammable system commercially available. Plus AVIUS is based on three years of clinically proven technology—a claim no other A-V sequential pacemaker can match.

### THE MOST MULTIPROGRAMMABLE, TECHNOLOGICALLY ADVANCED SYSTEM TODAY.

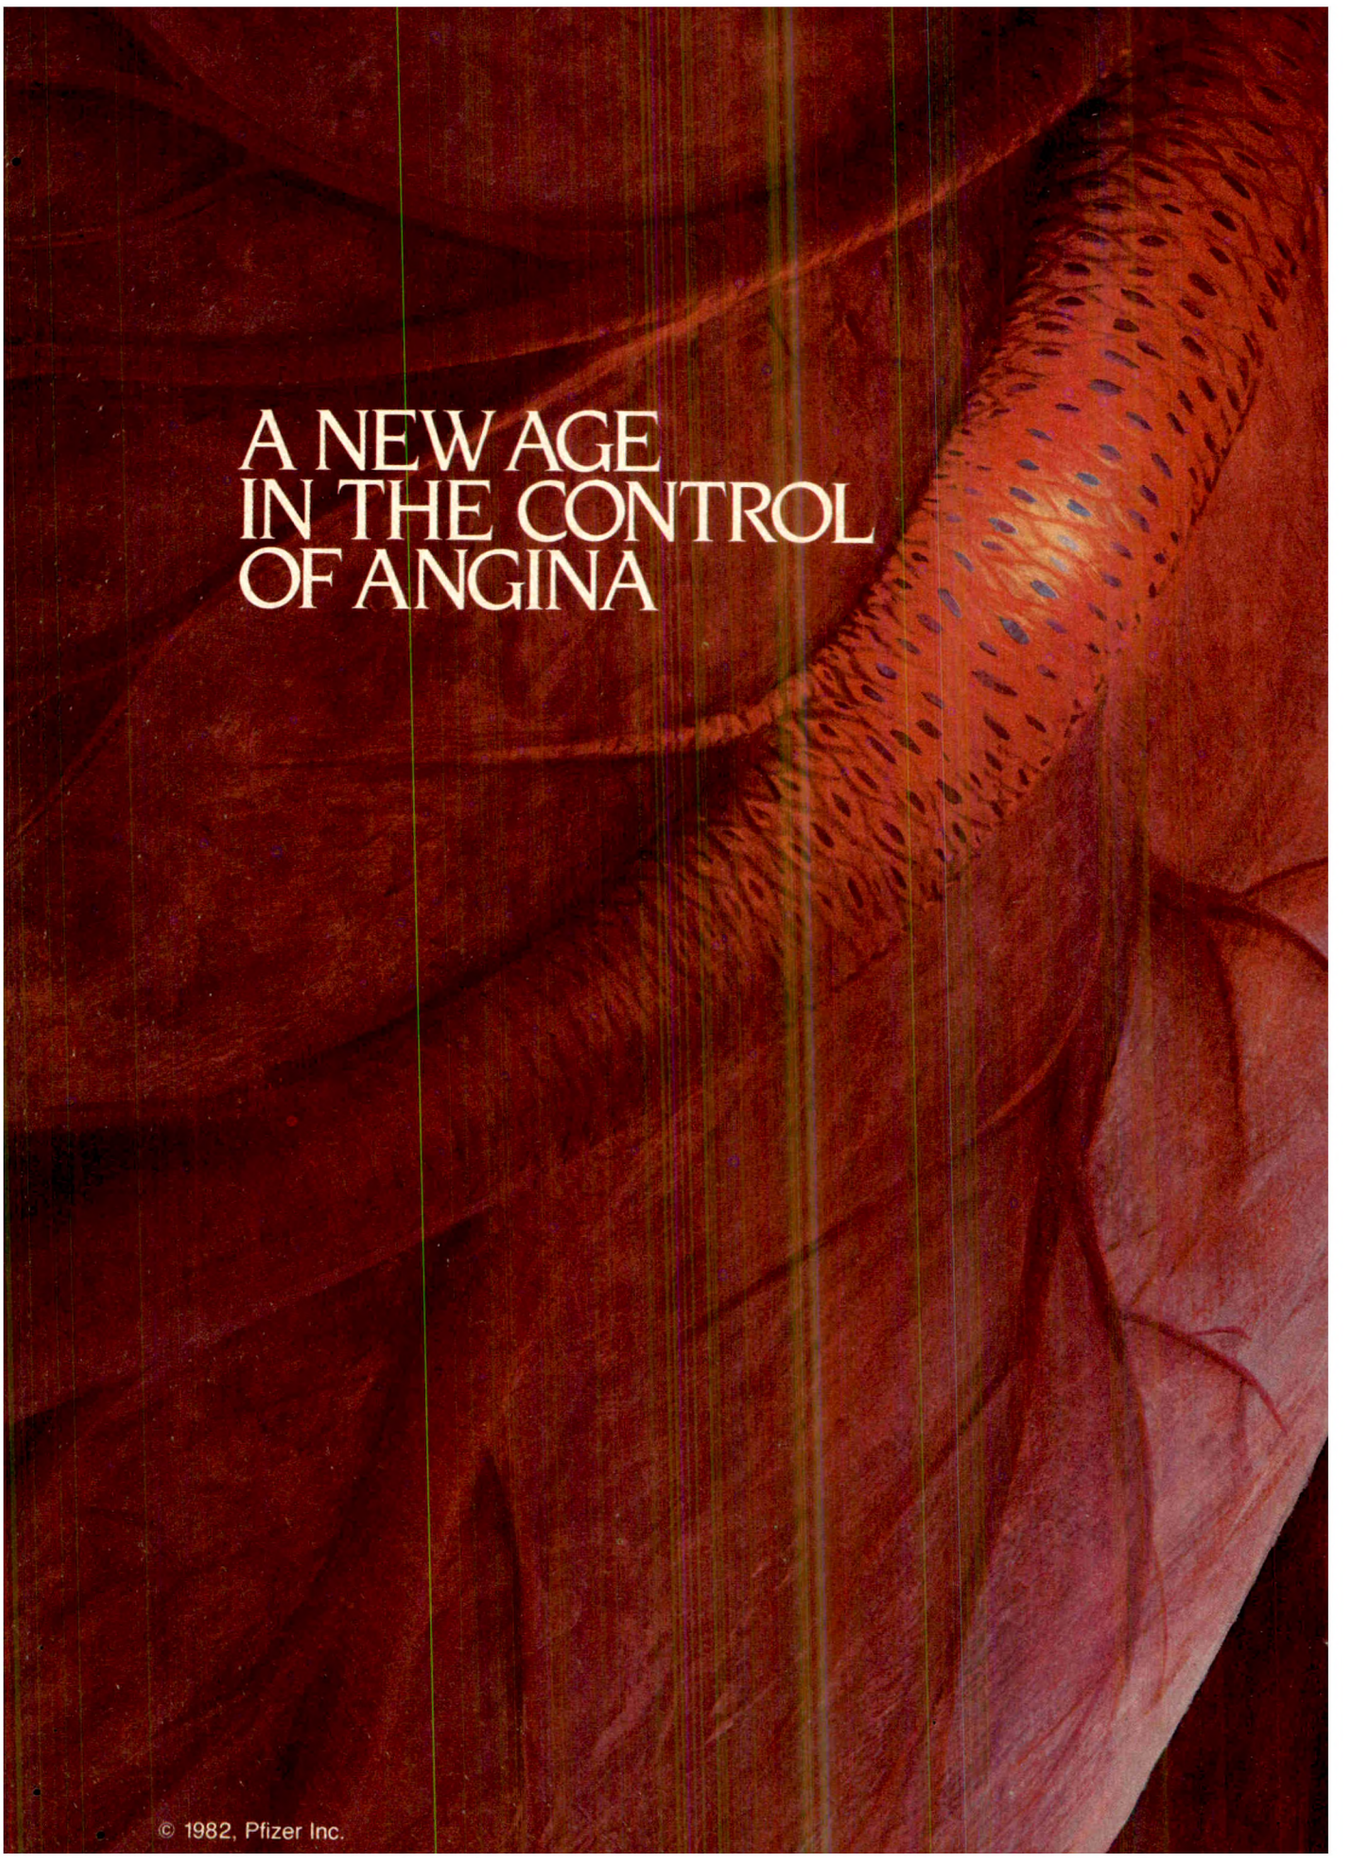
AVIUS continues to offer more programming options than any other A-V sequential pacemaker. It's multiprogrammable in A-V sequential (DVI), Demand Ventricular (VVI) and Asynchronous A-V sequential (DOO) modes. The sophisticated, easy-to-use programmer allows you to select among 15 pulse rates, 15 pulse widths and 7 sensitivity levels.

The EKG transmitter, A-V mini-clinic and flexible, PolyFlex® pacing leads complete the technologically advanced AVIUS system.

### AVIUS—THE CONFIDENT CHOICE.

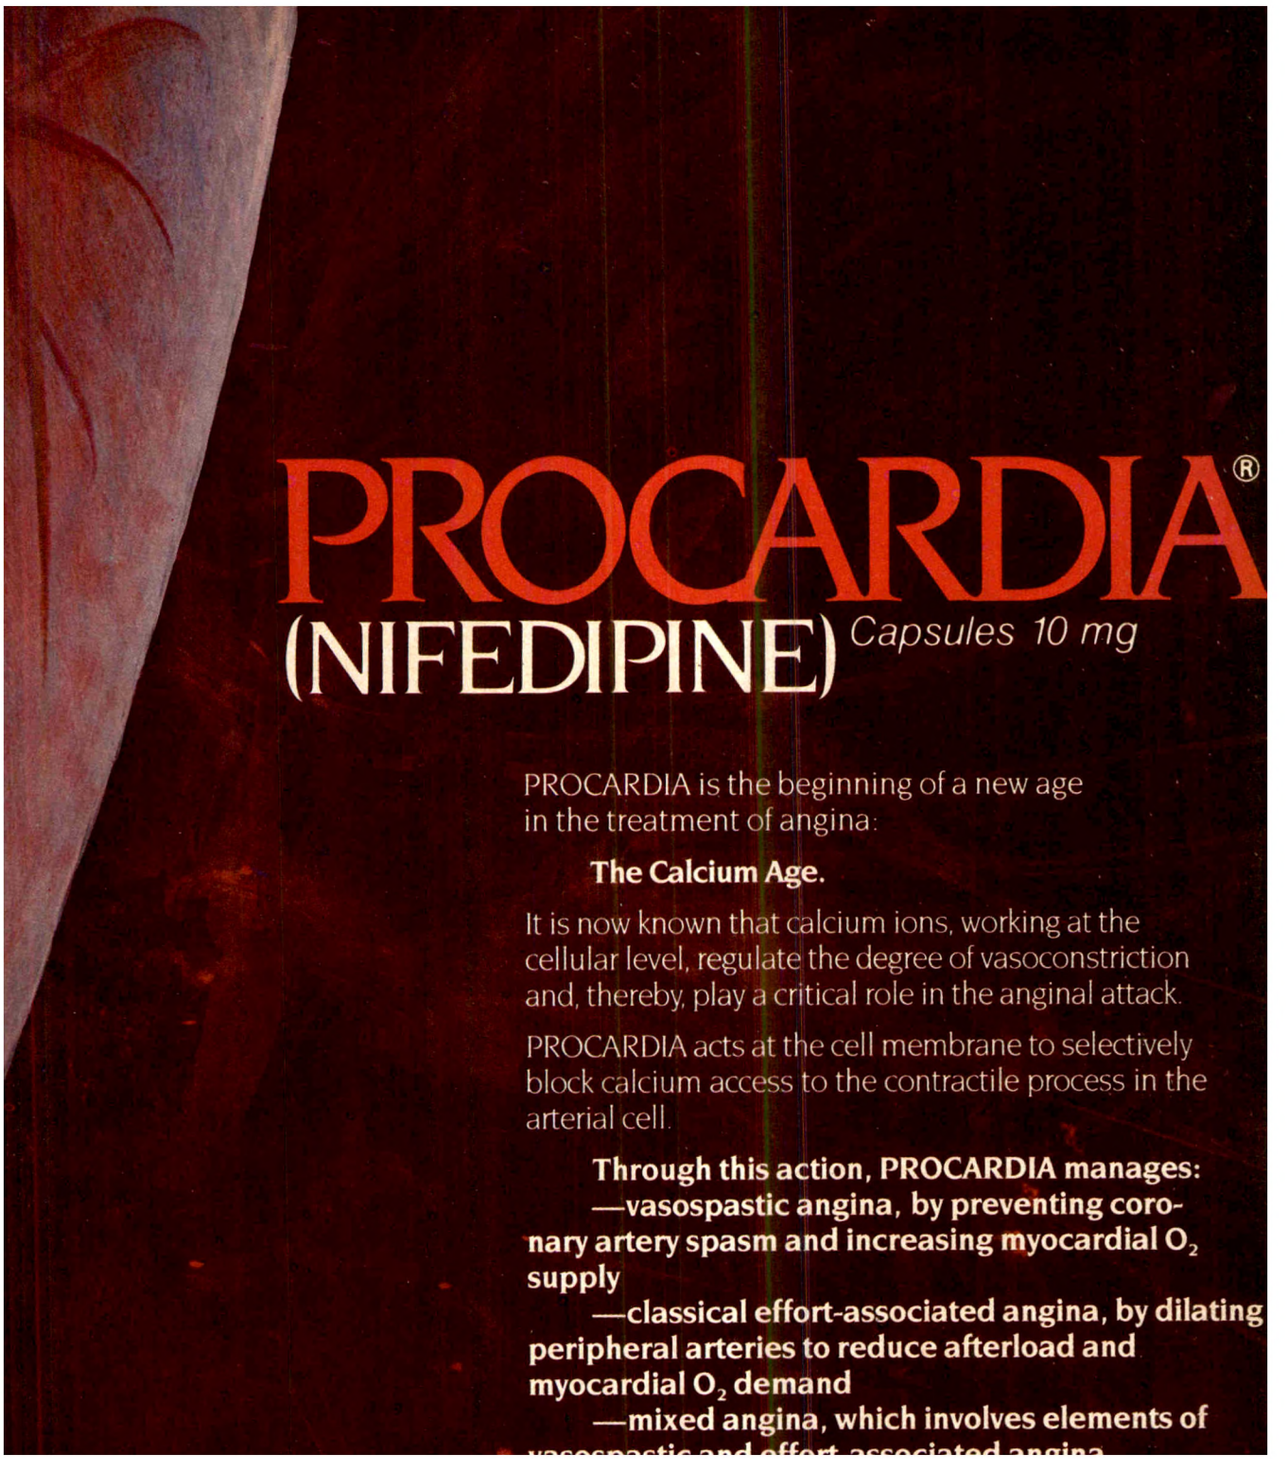
A-V sequential pacing in many cases has proven superior to standard ventricular pacing in achieving optimum cardiac output and efficiency. Consequently, many patients feel better and can enjoy a more active life. With Intermedics' record of technological achievement and clinical effectiveness, you can be confident that AVIUS is the pacemaker of choice for your patients who will benefit from A-V sequential pacing. Be confident with the only commercially available, compact, A-V sequential pacemaker, by contacting your nearest Intermedics representative, or calling us toll free at 1-800-231-2330 (in Texas call 1-800-392-3726).

Intermedics Inc.™
P.O. Box 617
Freeport, Texas 77541



**Our Business is Life.®**

INDICATIONS FOR USE: Implantable cardiac pulse generators may be indicated for long-term treatment of impulse formation or conduction disorders resulting in symptomatic bradyarrhythmias, and heart block unresponsive to drug therapy.



A-V sequential pacing is specifically indicated for treatment of conduction disorders that require restoration of both rate and atrio-ventricular synchrony. A-V sequential pacing may also be indicated for patients with extensive myocardial infarction with A-V block and sinus bradycardia.

CONTRAINDICATIONS AND SIDE EFFECTS: There are no known contraindications to the use of pacemakers as a medical method for control of heart rate. Body rejection phenomena, local tissue reaction or skin necrosis, muscle and nerve stimulation, embolism, and cardiac tamponade have been reported.

PRECAUTIONS: See the "Cautionary notes" section of the Physicians' Manual for the Intermedics cardiac pulse generator to be implanted. Discussion includes Possible Complications, Environmental Hazards (electrocautery, diathermy, defibrillation, therapeutic radiation, home appliances, and industrial and special environments), and Effects of Drugs.

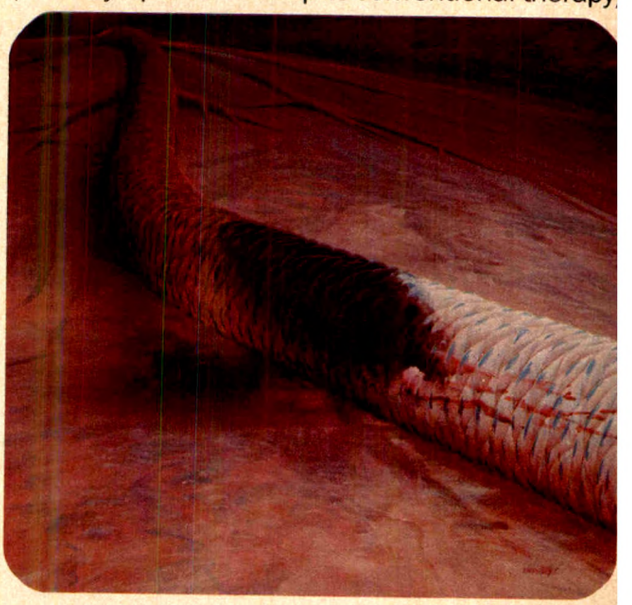
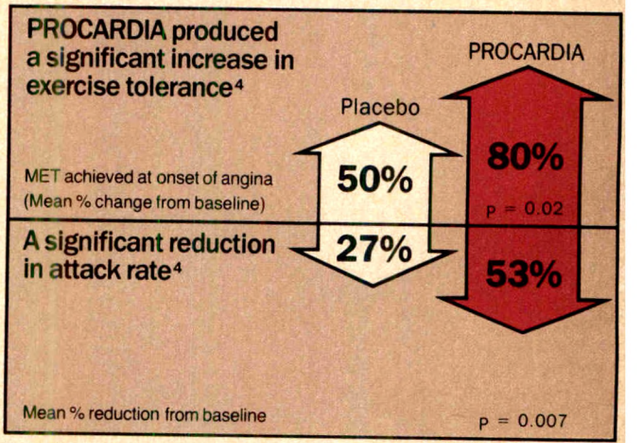
PROCARDIA®
(NIFEDIPINE) Capsules 10 mg
PROCARDIA is the beginning of a new age in the treatment of angina:
The Calcium Age.
It is now known that calcium ions, working at the cellular level, regulate the degree of vasoconstriction and, thereby, play a critical role in the anginal attack.
PROCARDIA acts at the cell membrane to selectively block calcium access to the contractile process in the arterial cell.
Through this action, PROCARDIA manages:
—vasospastic angina, by preventing coronary artery spasm and increasing myocardial $O_2$ supply
—classical effort-associated angina, by dilating peripheral arteries to reduce afterload and myocardial $O_2$ demand
—mixed angina, which involves elements of



# PROCARDIA®
## (NIFEDIPINE) *Capsules 10 mg*

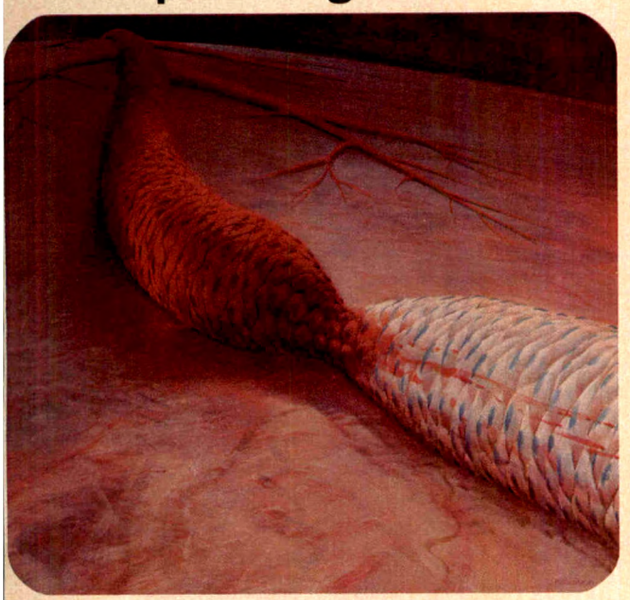


# PROVEN EFFECTIVE ACROSS THE SPECTRUM OF ANGINA

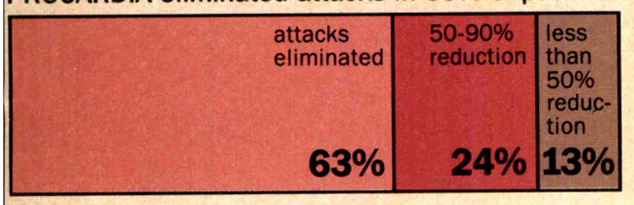
Contemporary medical opinion holds that the pathophysiology of angina is a spectrum ranging from pure, fixed atherosclerotic lesion to pure coronary artery spasm. Many patients, however, are believed to have a combination of both lesion and spasm.[2,3]

Angina due to pure fixed lesion can be prevented by reducing oxygen demand. Angina due to coronary artery spasm can be treated by preventing the spasm itself, thereby increasing oxygen supply. With this new understanding of angina, optimal antianginal therapy should provide this dual action: increasing $O_2$ supply while reducing $O_2$ demand.

## In effort angina*
(when symptomatic despite conventional therapy)

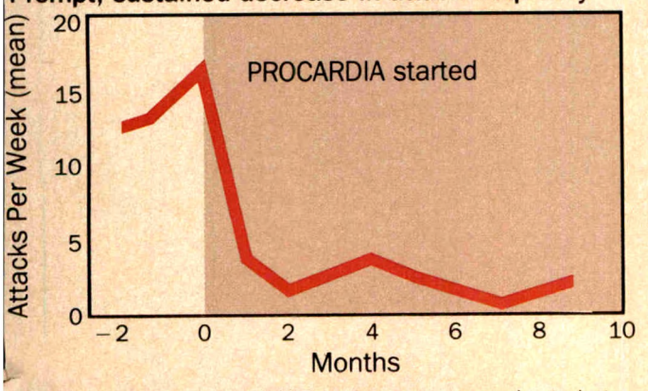


Double-blind, placebo-controlled, crossover 20-week study of 32 patients (27 evaluated for attack rate; 19 for exercise tolerance). Mean PROCARDIA dosage: 51 mg/day.



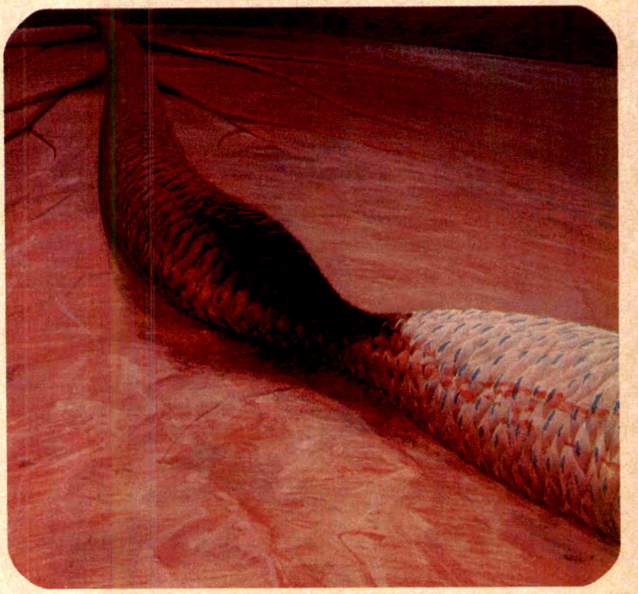
*In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

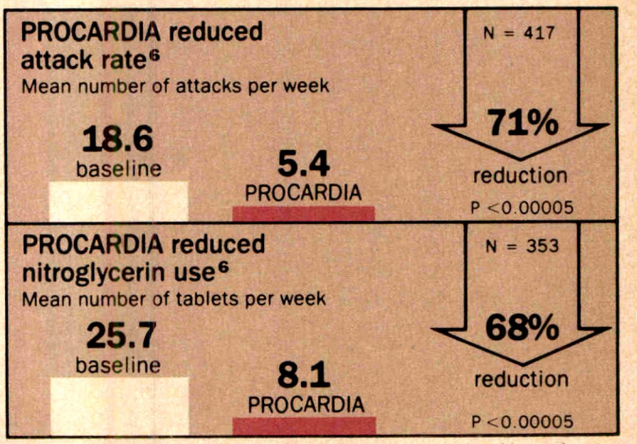
*Please see PROCARDIA Brief Summary on last page.*



## In vasospastic angina

**PROCARDIA eliminated attacks in 63% of patients[5]**





**Prompt, sustained decrease in attack frequency[5]**

Long-term, open study of 127 patients unresponsive to beta blockers and/or nitrates with symptoms of myocardial ischemia and demonstrated coronary artery spasm. PROCARDIA dosage: 40 to 160 mg/day.

## In mixed angina (fixed lesion and spasm)

Studies of patients with mixed angina characterized by pain at rest and effort. Most patients (89%) were initiated on nitrate and/or beta blocker therapy but remained symptomatic. Minimum duration of nifedipine treatment two months. Nifedipine dosage: 30 to 120 mg/day.

PROCARDIA®
THE FIRST ORAL CALCIUM CHANNEL BLOCKER

# PROCARDIA®
## (NIFEDIPINE) *Capsules 10 mg*

# ANGINA MANAGEMENT BEYOND BETA BLOCKERS

—Beta blockers prevent angina primarily by lowering myocardial oxygen demand. Like these agents, PROCARDIA reduces myocardial oxygen demand. However, PROCARDIA provides an added dimension of angina control by increasing myocardial oxygen supply where coronary artery spasm is present.

—Beta blockers can actually cause spasm. PROCARDIA prevents spasm.

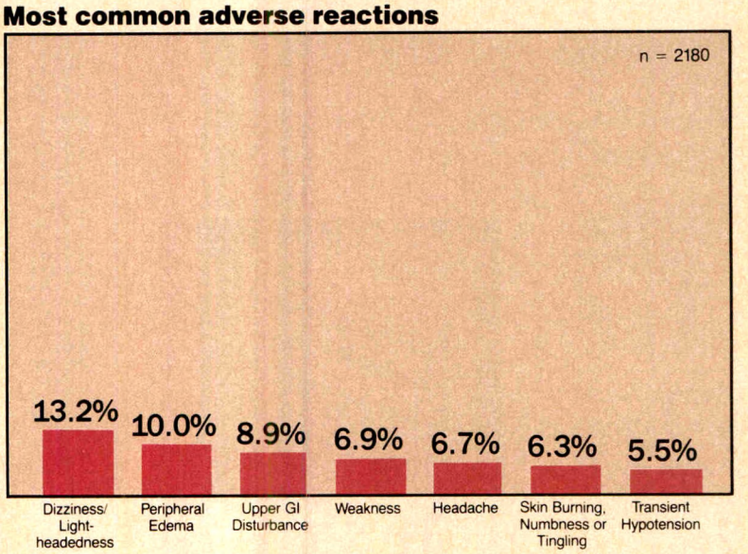
—Beta blockers decrease myocardial perfusion in poststenotic areas. PROCARDIA increases myocardial perfusion to both normal and poststenotic areas.

—Beta-blocker treatment is limited in patients with myocardial dysfunction, COPD, asthma, bundle branch blocks, and diabetes. PROCARDIA can be given safely in all these groups of patients.

—The hypotensive effect of PROCARDIA is usually modest and well tolerated, however, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or subsequent upward dosage adjustment, and may be more likely with concomitant beta blockers.

—Occasional patients have developed well-documented increased frequency, duration or severity of angina on starting PROCARDIA, or at the time of dosage increases. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers, if possible, rather than stopping them abruptly before beginning PROCARDIA.

—Rarely, patients usually receiving a beta blocker have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.



*Please see PROCARDIA Brief Summary on last page.*

# THE FIRST ORAL CALCIUM CHANNEL BLOCKER...

# PROVIDES PROTECTION WITH A MILD SIDE-EFFECT PROFILE

**Most common adverse reactions**

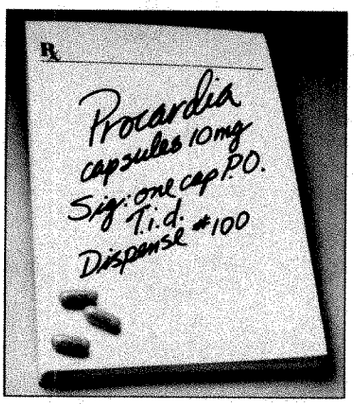
Information is drawn from a large uncontrolled experience in 2180 patients and presents the most frequent side effects reported with PROCARDIA.

# AN ADDED ADVANTAGE: COMPATIBILITY

—MAY BE USED WITH A WIDE VARIETY OF OTHER AGENTS

—CAN BE USED WITH NITRATES AND BETA BLOCKERS WITH CAUTION (See Warnings and Precautions)

# THE FIRST ORAL CALCIUM CHANNEL BLOCKER FOR THE MANAGEMENT OF ANGINA



# PROCARDIA®

## PROCARDIA® CAPSULES (nifedipine) For Oral Use

**BRIEF SUMMARY**

**INDICATIONS AND USAGE: I. Vasospastic Angina:** PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

**II. Chronic Stable Angina (Classical Effort-Associated Angina):** PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta-blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See Warnings.)

**CONTRAINDICATIONS:** Known hypersensitivity reaction to PROCARDIA.

**WARNINGS: Excessive Hypotension:** Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

**Increased Angina/Beta Blocker Withdrawal:** Occasional patients have developed well documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

**Congestive Heart Failure:** Rarely, patients usually receiving a beta blocker have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

**PRECAUTIONS: General:** Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See Warnings.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

**Pregnancy:** Category C.

**ADVERSE REACTIONS:** The most common adverse events include dizziness or light-headedness, peripheral edema, nausea, weakness, headache and flushing each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

**Laboratory tests:** Rare, mild to moderate, transient elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT, and SGPT have been noted, and a single incident of significantly elevated transaminases and alkaline phosphatase was seen in a patient with a history of gall bladder disease after about eleven months of nifedipine therapy. The relationship to PROCARDIA therapy is uncertain. These laboratory abnormalities have rarely been associated with clinical symptoms.

**HOW SUPPLIED:** Each orange, soft gelatin PROCARDIA Capsule contains 10 mg of nifedipine. PROCARDIA Capsules are supplied in amber glass bottles of 100 capsules (NDC 0069-2600-66).

The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

# Electrophysiologic Testing in the Management of Survivors Of Out-of-Hospital Cardiac Arrest

FRED MORADY, MD, MELVIN M. SCHEINMAN, MD, DAVID S. HESS, MD, RUEY J. SUNG, MD, EDWARD SHEN, MD, and WILLIAM SHAPIRO, MD

**Forty-five patients survived a cardiac arrest due to ventricular tachycardia (VT) or ventricular fibrillation (VF). Programmed ventricular stimulation was performed with the patients taking no antiarrhythmic medications. Sustained VT was induced in 26 patients (58%) and nonsustained VT in 8 (18%). With treatment aimed at the underlying heart disease (plus empiric antiarrhythmic therapy in 2 patients), the 11 patients who had no inducible VT have had no recurrence of symptomatic VT or cardiac arrest over a follow-up period of 19 ± 9 months (mean ± standard deviation). Conventional antiarrhythmic drugs suppressed the induction of VT and were used for chronic treatment in 9 of 34 patients (26%) with inducible VT. Three of these 9 patients had recurrent VT or sudden death, whereas 6 have had no recurrence over follow-up of 20 ± 7 months. In the 25 of 34 patients in whom the induction of VT was not suppressed by conventional antiarrhythmic drugs, 23 were treated with amiodarone (daily dose 550 ± 120 mg), and 2 underwent coronary artery bypass grafting with either aneurysmectomy or map-directed endocardial resection. One of the latter 2 patients died suddenly 12 months after surgery. Among the 23 patients treated with amiodarone, 2 had fatal VT or sudden death and 21 (91%) did not, over 18 ± 14 months of follow-up.**

**In survivors of a cardiac arrest, the chief value of electrophysiologic testing is in identifying patients without inducible VT, who appear to have a low risk of recurrent sudden death with treatment directed at the underlying heart disease. Serial electropharmacologic testing with conventional antiarrhythmic drugs is disappointing, with a low incidence of arrhythmia suppression.**

Of patients who have survived an episode of out-of-hospital cardiac arrest, 29 to 74% have been reported to have inducible VT with programmed ventricular stimulation.[1-3] Only 1 study has reported long-term follow-up events in patients who had aborted cardiac arrest and in whom chronic antiarrhythmic therapy was based on the results of electropharmacologic testing. Ruskin et al[2] reported no recurrence of cardiac arrest over a mean follow-up of 15 months in 19 patients treated with drugs that suppressed the induction of VT. We performed electrophysiologic testing in 45 survivors of out-of-hospital cardiac arrest; the results of therapy guided by electropharmacologic drug testing are reported herein.

## Methods

Forty-five patients (Table I) survived an out-of-hospital episode of cardiac arrest. The earliest rhythm documented before direct-current cardioversion was VF in 30 and VT in 12; in 3 patients the rhythm before direct-current cardioversion was not documented. At the time of the cardiac arrest, 31 of 45 patients had been taking 1 of the following antiarrhythmic drugs orally: quinidine, 0.8 to 1.2 g/day; procainamide, 2 to 3 g/day; disopyramide, 0.6 g/ day; or phenytoin, 300 mg/day. In addition, 14 patients were taking propranolol, 80 to 240 mg/day.

Coronary angiography was performed within 3 weeks of the episode of aborted cardiac arrest in 31 of 45 patients, including 26 of 36 patients who had ischemic heart disease. Left ventricular (LV) ejection fraction was determined either by contrast or radionuclide angiography in 41 of 45 patients.

Patients with evidence of a new myocardial infarction in association with the episode of aborted cardiac arrest were excluded from the study. In addition, patients with the congenital long Q-T syndrome were excluded because of the previous finding that programmed ventricular stimulation seldom results in VT induction in these patients.[4]

**Electrophysiologic study protocol:** After informed consent had been obtained, an electrophysiologic study was performed 5 days to 6 weeks after the episode of cardiac arrest. All antiarrhythmic medications were discontinued for at least 4 half-lives before electrophysiologic study. Studies were performed in the fasting, unsedated state. Two quadripolar electrode catheters were inserted percutaneously into a femoral vein; 1 was positioned across the tricuspid valve for recording the His bundle electrogram, and the other was positioned against the apex of the right ventricle. In patients undergoing left ventricular stimulation, a bipolar electrode catheter was inserted percutaneously into a femoral artery and positioned against the apex of the left ventricle. Electrocardiographic leads $V_1$, I, and III and intracardiac electrograms were recorded using a VR-12 Electronics for Medicine recorder. Ventricular stimulation was performed with 2 ms pulses, delivered by a programmable stimulator (Bloom) at a constant current of 5 mA.

The following stimulation protocol was used. Right ventricular drive was instituted at a cycle length of 500 ms and diastole was scanned with 1, 2, and then 3 extrastimuli. Short bursts of right ventricular overdrive pacing were then performed at cycle lengths of 600 to 300 ms. If VT was not induced with right ventricular stimulation, left ventricular stimulation was performed, except in 1 patient who had a prosthetic aortic valve and 3 patients we studied early in our experience. In patients who did not have ischemic heart disease, if VT was not induced with this protocol, ventricular stimulation was repeated during continuous infusion of 1 to 5 μg/min of isoproterenol, titrated to maintain a heart rate of 120 beats/min.

In patients who did not have inducible VT, a standard atrial pacing protocol was used to rule out rapid supraventricular tachycardia as a cause of cardiac arrest. Sustained VT was defined as VT at least 30 seconds in duration or requiring direct-current cardioversion or overdrive pacing for termination. Nonsustained VT was defined as VT of 6 beats to 30 seconds in duration.

**Electropharmacologic testing:** Drugs were tested based on each patient's history of drug intolerance and previous clinical response. The following drugs were tested acutely in the electrophysiology laboratory after intravenous administration: procainamide, 750 to 1,500 mg; propranolol, 0.2 mg/kg; lidocaine, loading dose of 225 mg over 20 minutes, concomitant with a 2 mg/min continuous infusion; propafenone, loading dose of 2 mg/kg, concomitant with a 1 to 2 mg/min continuous infusion. The following oral agents were tested during the last 1 to 2 hours of the dosing interval, after administration of a sufficient number of doses to attain a steady-state serum drug level: procainamide, 3 to 8 g/day; quinidine, 1.2 to 1.6 g/day; disopyramide, 400 to 600 mg/day; propranolol, 160 to 480 mg/day; tocainide, 0.8 to 1.2 g/day; nadolol, 240 to 300 mg/day.

Electropharmacologic testing was usually performed until VT could no longer be induced by both right and left ventricular stimulation, even when VT had been induced by right ventricular stimulation in the baseline study; however, in 4 patients studied early in our experience and in whom VT was induced by right ventricular stimulation, left ventricular stimulation was not performed during electropharmacologic testing. If high-dose procainamide was not successful in suppressing VT induction, quinidine and disopyramide were generally not tested.

When the induction of VT could not be suppressed by 1 or more of the aforementioned drugs, treatment was begun with amiodarone, 800 mg/day orally, except in 2 patients who underwent a surgical procedure. Because of the observation by ourselves and others that ventricular stimulation studies are not predictive of clinical response in patients treated with amiodarone, patients treated with this drug did not undergo repeat studies.[5-7]

**TABLE I Clinical Characteristics of 45 Survivors of Cardiac Arrest***

| | |
|---|---|
| Age (yr) | 56 ± 16† |
| Males/females | 39/6 |
| Heart disease | |
| Ischemic | 36 (78) |
| Single-vessel CAD | 3 |
| Double-vessel CAD | 3 |
| Triple-vessel CAD | 16 |

**TABLE II Surgical Procedures Performed in 45 Survivors of Cardiac Arrest**

| Patients (n) | Heart Disease | Operative Procedure |
|---|---|---|
| | Before Electrophysiologic Testing | |
| 1 | Aortic stenosis | Aortic valve replacement |
| 2 | Stenosis of LMCA | CABG |
| | After Electrophysiologic Testing | |
| 1 | Stenosis of LMCA | CABG and aneurysmectomy |
| 1 | Triple-vessel CAD | CABG and map-directed endocardial resection |
| 1 | Triple-vessel CAD | CABG |

CABG = coronary artery bypass grafting; CAD = coronary artery disease; LMCA = left main coronary artery.

**Surgical therapy:** After their episodes of cardiac arrest, 3 patients underwent a surgical procedure before electrophysiologic testing and 3 afterwards (Table II).

**Chronic drug therapy and follow-up:** Patients were followed on a regular basis by either 1 of the investigators or by the patient's referring physician. Drug therapy was adjusted to yield serum drug levels that matched drug levels found to be successful in suppressing VT induction in the laboratory. In patients treated with amiodarone, the dose was tapered to 600 mg/day after 6 weeks of therapy; subsequent adjustments in the dose depended on the clinical response and development of adverse effects.

Twenty-four–hour ambulatory electrocardiographic recordings were obtained every 3 to 4 months. Sudden death was defined as unexpected natural death occurring during sleep or within 1 hour of the patient's collapse.

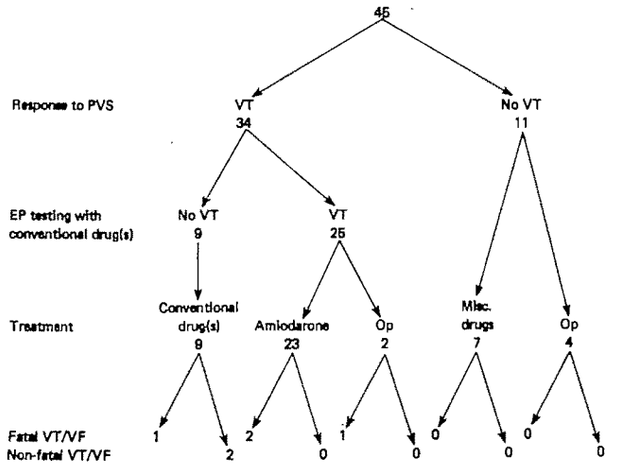

**FIGURE 1.** Results of electrophysiologic testing and clinical follow-up in 45 survivors of cardiac arrest. EP = electropharmacologic; Misc. = miscellaneous (see text for details); Op = operation (as listed in Table II); PVS = programmed ventricular stimulation.

**Statistical analysis:** Values are expressed as mean ± 1 standard deviation. Patients in whom VT induction was suppressed by conventional agents were compared with those in whom VT induction was not suppressed using Fischer's exact test and Student's *t* test.

## Results

During the baseline electrophysiologic study, sustained VT was induced in 26 of 45 patients (58%). Mean cycle length of VT was 273 ± 77 ms. The VT morphology was that of right bundle branch block in 18, left bundle branch block in 5, and polymorphic in 3. VT was induced with right ventricular stimulation in all but 3 patients who required left ventricular stimulation. VT was induced with burst pacing in 3 patients, with 1 extrastimulus in 1 patient, with 2 extrastimuli in 9 patients, with 3 extrastimuli in 12 patients, and with 3 extrastimuli during isoproterenol infusion in 1 patient. Direct-current cardioversion was required to terminate VT in 15 of 26 patients; in the remaining 11 patients, VT was terminated with overdrive pacing.

Nonsustained VT was induced in 8 of 45 patients (18%). The mean duration of VT was 29 ± 18 beats (range 8 to 65); the mean cycle length was 224 ± 19 ms. The VT morphology was that of right bundle branch block in 4 patients, left bundle branch block in 1, and polymorphic in 3. In all cases, nonsustained VT was induced with right ventricular stimulation; 2 extrastimuli were necessary in 2 patients, and 3 extrastimuli in 6.

Overall, VT was induced with programmed ventricular stimulation in 34 of 45 patients (76%). Of the 30 patients who had VF at the time of resuscitation, VT was induced in 23 (77%); of the 12 patients who had VT at the time of resuscitation, VT was induced in 10 (83%).

VT could not be induced with programmed ventricular stimulation in 11 patients (24%). Two of these patients had undergone coronary artery bypass grafting because of stenosis of the left main coronary artery, and 1 had undergone aortic valve replacement for aortic stenosis. A fourth patient had had a cardiac arrest 2 weeks after initiation of quinidine for prevention of atrial fibrillation; an electrocardiogram obtained several days before the cardiac arrest showed a Q-T interval of 0.52 seconds ($Q\text{-}T_c$ = 0.58 second). A fifth patient who had coronary artery disease (CAD) had no inducible VT despite frequent episodes of spontaneous VT before and after electrophysiologic study. Of the other 6 patients, 5 had CAD and 1 had coronary artery spasm. Three of these patients were engaged in strenuous exertion at the time of the cardiac arrest. One patient had no underlying heart disease.

**Clinical follow-up in patients with no inducible VT during baseline study (Fig. 1):** Eleven patients with no inducible VT have had no recurrence of symptomatic VT or VF over a mean follow-up period of 19 ± 9 months (range 9 to 34). Four patients underwent coronary artery bypass grafting or aortic valve replacement (before the electrophysiologic study in 3 patients and afterwards in 1). The patient who had coronary artery spasm was treated with nitrates. Three patients who had CAD but who either refused or were not suitable candidates for coronary artery bypass grafting were treated with nitrates and beta-adrenergic blocking agents aimed at preventing myocardial ischemia; 1 of these patients was also treated with encainide for suppression of asymptomatic premature ventricular beats. The patient who had been treated with quinidine and had Q-T interval prolongation before a cardiac arrest was treated with procainamide (for paroxysmal atrial fibrillation); no VT could be induced while taking procainamide. The patient who had no inducible VT but who had frequent spontaneous episodes of VT was treated with amiodarone. The patient without underlying heart disease was initially treated empirically with nadolol for 6 months and has subsequently taken no medication over an additional 7 months of follow-up.

**Results of electropharmacologic drug testing and clinical follow-up (Fig. 1):** VT could no longer be induced after administration of a conventional antiarrhythmic drug in 9 of 34 patients (26%) who had inducible VT during the baseline electrophysiologic study. Induction of VT was suppressed by procainamide in 4 patients (mean serum level 10.3 ± 5.9 μg/ml), quinidine in 1 (serum level 3.2 μg/ml), nadolol or propranolol in 2, and a combination of procainamide (serum level 6.4 ± 0.9 μg/ml) and propranolol in 2. These patients were treated chronically with the drug(s) that suppressed the induction of VT. One patient died suddenly after 1 month of treatment. Another patient (who did not undergo left ventricular stimulation during electropharmacologic testing) had an episode of symptomatic VT after 1 week of treatment, underwent coronary bypass grafting, and has had no recurrence of VT or cardiac arrest over 21 months of follow-up. A third patient had recurrence of aborted cardiac arrest after 17 months of treatment, and subsequently underwent insertion of an

automatic internal defibrillator. The remaining 6 of 9 patients had no recurrence of cardiac arrest or symptomatic VT over a mean follow-up period of 20 ± 7 months.

During electropharmacologic testing with conventional antiarrhythmic drugs, VT remained inducible in 25 of 34 (74%) patients who had inducible VT during the baseline electrophysiologic study. These patients underwent an average of 1.8 drug trials each. Twenty-one of these 25 patients failed testing with intravenous procainamide (mean serum level 12.9 ± 6.8 μg/ml). There was no significant difference in the proportion of patients with ischemic heart disease (20 of 25 versus 5 of 9) or mean ejection fraction (0.38 ± 0.10 versus 0.46 ± 0.15) in these 25 patients and the 9 in whom VT induction was suppressed by a conventional antiarrhythmic drug. One of these 25 patients underwent coronary artery bypass grafting and aneurysmectomy and died suddenly 12 months after surgery. Another patient underwent coronary artery bypass grafting and map-directed endocardial resection and has remained well for 39 months. The remaining 23 of 25 patients were treated with amiodarone (mean dose 550 ± 120 mg) either alone (17 patients) or in combination with procainamide (in 6 patients procainamide slowed the rate of induced VT). One patient died suddenly after 1 month of treatment, and another patient died from refractory VT after 3 months of treatment. The remaining 21 of 23 patients (91%) who were treated with amiodarone have had no recurrence of cardiac arrest or symptomatic VT over a mean follow-up period of 18 ± 14 months (range 7 to 65).

Overall, in the 45 patients who survived a cardiac arrest and underwent electrophysiologic testing, 4 of 45 patients (9%) died due to VT or VF at 4.2 ± 5 months of follow-up, 2 of 45 (4%) had a nonfatal recurrence of VT at 1 week and 17 months of follow-up, and 39 of 45 (87%) have had no recurrence of symptomatic VT or VF over a follow-up period of 18 ± 12 months.

## Discussion

Previous studies have shown that patients who survive an episode of cardiac arrest in the absence of a transmural myocardial infarction and who are treated with conventional antiarrhythmic drugs in a nonstandardized fashion have a mortality of 34 to 36% at 1 year of follow-up.[8–10] In comparison, in the present series of 45 patients in whom therapy was guided by the results of electrophysiologic testing and in whom amiodarone was used in 50% of patients, the mortality from VT or VF was only 9% at 1.5 years of follow-up. The lower mortality in the present series suggests that electrophysiologic testing and/or the use of amiodarone may play a role in improving survival in a group of patients at high risk of sudden death.

The finding of inducible VT in 76% of patients who survived a cardiac arrest is similar to the findings of Josephson,[3] Ruskin,[2] and their co-workers, who reported inducible VT in 60 and 74% of such patients, respectively. In contrast, Myerburg et al[1] found that only 29% of patients who had survived a cardiac arrest had inducible VT. However, in the last series, only 1 extrastimulus was used in the ventricular stimulation protocol, compared with 2 extrastimuli in the series of Josephson and Ruskin and 3 extrastimuli in our series. Thus, programmed ventricular stimulation should be performed with at least 2 extrastimuli to avoid false-negative results. The relative sensitivity and specificity of 2 versus 3 extrastimuli remain to be determined.

Left ventricular stimulation was required to induce VT in approximately 10% of patients who had inducible VT. However, we performed right ventricular stimulation at only 1 site, the apex. It is possible that right ventricular stimulation at more than 1 site may at times eliminate the need for left ventricular stimulation. In any case, to maximize the yield of VT induction studies, ventricular stimulation should be performed at more than 1 site.

In the patients in this series who did not have inducible VT with programmed ventricular stimulation, possible reasons for its lack include the following: (1) The spontaneous arrhythmia may have been due to abnormal automaticity rather than reentry and thus may not be provocable with programmed stimulation. This is the most likely explanation in the patient who had no inducible VT despite having frequent spontaneous episodes of VT before and after the electrophysiologic study. (2) The onset of spontaneous VT or VF may have been related to transient myocardial ischemia that was not present at the time of the ventricular stimulation study. This is a likely explanation in the patient who had coronary spasm, in the 2 patients who had stenosis of the left main coronary artery and underwent coronary artery bypass grafting before the ventricular stimulation study, and in the 3 patients with CAD who experienced a cardiac arrest during strenuous exertion. (3) The spontaneous episode of VT or VF was related to an abnormality that was corrected by the time of the electrophysiologic study (for example, hypokalemia, quinidine-induced Q-T prolongation, or aortic stenosis). Thus, in 2 of our patients the lack of inducible VT can be attributed to discontinuation of quinidine in 1 and aortic valve replacement in the other. In patients who survive a cardiac arrest and do not have inducible VT, another possible explanation for the lack of inducible VT may be that the patient has the congenital long Q-T syndrome; VT can be induced with programmed stimulation in only a minority of these patients.[4]

In the series by Ruskin et al,[2] 6 patients who had survived a cardiac arrest did not have inducible VT; these patients were not treated with antiarrhythmic drugs and had no recurrence of cardiac arrest over a mean follow-up of 15 months. However, no details of their treatment, such as surgery or antianginal drugs, were given. The 11 patients in our series who did not have inducible VT also have had no recurrence of symptomatic VT or VF. Only 2 of 11 patients were treated with antiarrhythmic drugs specifically aimed at suppressing ventricular arrhythmias. Thus, in patients who have survived a cardiac arrest, electrophysiologic testing may be helpful in identifying those with

a low risk of recurrent VT or VF when treatment is directed toward the underlying heart disease without specific antiarrhythmic therapy.

In the patients in whom VT was induced with programmed ventricular stimulation, electropharmacologic testing with conventional antiarrhythmic drugs was disappointing, with suppression of VT induction in only 26%. Of the patients in whom the induction of VT could not be suppressed, 21 of 25 were tested with large doses of procainamide. Although most of these patients were not tested with a second type I antiarrhythmic drug, it is unlikely that such testing would have been successful in suppressing the induction of VT, since Waxman et al[11] reported that in 63 patients who had inducible VT with procainamide, only 9% of 144 additional drug trials with conventional agents were successful in suppressing VT induction. Similarly, in the series by Ruskin et al,[2] conventional antiarrhythmic drugs were successful in suppressing the induction of VT in only 34% of patients undergoing electropharmacologic testing. Electrophysiologic testing is therefore helpful in the management of patients with aborted cardiac arrest by identifying the large subgroup of patients who should be treated wtih investigational drugs or surgery.

Of the 9 patients who were treated with conventional drugs that suppressed the induction of VT during electropharmacologic testing, 3 had a recurrence of VT or VF despite continued treatment with the original drug regimen. Thus, the suppression of inducible VT during electropharmacologic testing in patients who have survived a cardiac arrest may not guarantee a successful long-term clinical response. Discordance between the results of acute drug testing and the chronic clinical response may be a result of progression of the underlying heart disease or fluctuations in other variables that may influence the propensity to develop VT or VF, such as sympathetic tone and the degree of myocardial ischemia.

Of the 23 patients who were treated with amiodarone, 92% have remained free of symptomatic VT or VF over 18 months of follow-up. Previous studies have also reported an excellent response to amiodarone in patients with recurrent VT or VF.[6,12,13] We and others have demonstrated that the induction of VT during chronic oral amiodarone therapy does not preclude a good clinical response.[5–7] Therefore, in our series no further electropharmacologic testing was performed when patients were treated with amiodarone.

In light of the excellent response in the subgroup of patients treated with amiodarone, an alternate approach to electropharmacologic testing in the management of patients who have survived a cardiac arrest might be simply to treat all such patients empirically with amiodarone. This approach was employed by Peter et al[14] in 27 patients who had survived a cardiac arrest; these patients were treated empirically with amiodarone without undergoing an electrophysiologic study. The recurrence rate of VT or VF was only 7% at the end of 1 year of treatment. The principal disadvantage of this approach is that those patients who would have responded to conventional drugs are exposed to the risks of therapy with an experimental agent.

In summary, the following conclusions can be drawn from our study of 45 patients who survived a cardiac arrest: (1) VT can be induced in 76% of patients. (2) The lack of inducible VT may identify patients who have a low risk of recurrent VT or sudden death when therapy is directed toward the underlying cardiac abnormality. (3) Electropharmacologic testing with conventional antiarrhythmic drugs is disappointing, with a minority (26%) of patients responding to these drugs. (4) In the patients who do not respond to electropharmacologic testing with conventional drugs, treatment with amiodarone is associated with a low recurrence rate of VT or sudden death. If the favorable outcome of amiodarone therapy in these patients is confirmed, empiric trials with this drug would be indicated, obviating serial electropharmacologic testing.

# Quinidine for Ventricular Arrhythmias: Value of Electrophysiologic Testing

JOHN P. DiMARCO MD, PhD, HASAN GARAN, MD, and JEREMY N. RUSKIN, MD

**Quinidine was evaluated during serial electrophysiologic testing with programmed ventricular stimulation in 89 patients with life-threatening ventricular arrhythmias. In 30 of the 89 patients, quinidine therapy prevented the initiation of ventricular tachycardia (VT) during programmed ventricular stimulation. In 8 additional patients no single drug tested was effective, and quinidine in combination with either mexiletine (7 patients) or propranolol (1 patient) prevented the initiation of VT during electrophysiologic testing. The mean serum concentrations of quinidine in the patients who responded and those who failed to respond were 2.9 ± 0.8 and 2.8 ± 1.1 μg/ml, respectively; however, but nonresponders were characterized by more severe congestive heart failure and an increased incidence of digitalis use. During chronic therapy (24 ± 3 months) with quinidine either alone or in combination with a second antiarrhythmic drug in the 38 patients whose arrhythmia had been suppressed during electrophysiologic testing, 32 (84%) remain symptom-free while 3 have had recurrent arrhythmia and 3 discontinued quinidine because of adverse effects. These data demonstrate that quinidine, when selected on the basis of electrophysiologic testing, provides effective long-term prophylaxis against recurrent ventricular arrhythmia and that approximately 40% of patients tested are likely to respond either to quinidine alone or quinidine in combination with another antiarrhythmic agent.**

Quinidine, a cinchona alkaloid, has been known to have electrophysiologic effects for over 200 years.[1] Its successful use in the treatment of VT was reported early in this century. Since that time it has remained one of the principal drugs used for prophylaxis against recurrent VT.[2,3] Within the last 10 years, electrophysiologic testing with programmed ventricular stimulation has become established as a method for assessing antiarrhythmic therapy in patients with ventricular arrhythmias. In this report we describe the effects of quinidine observed during electrophysiologic testing in 89 patients with ventricular arrhythmias.

## Methods

We administered quinidine to 89 patients with a history of 1 or more clinical episodes of either VT or ventricular fibrillation (VF) during an evaluation that utilized intracardiac electrophysiologic techniques. In 86 of 89 patients, VT or VF had been initiated by programmed cardiac stimulation during a baseline study performed 48 or more hours after discontinuation of any previous antiarrhythmic therapy. In the remaining 3 patients, multiple episodes of VT or VF occurred when attempts were made to withdraw therapy; these 3 patients underwent the initial electrophysiologic study while receiving quinidine. Patients referred to our laboratory with a history of an allergic reaction to quinidine were not rechallenged with the drug. Patients who had previously had VT or VF during chronic therapy with quinidine were also excluded if documentation of an adequate serum level at the time was available. The clinical characteristics of the 89 patients included in this report are listed in Table I.

**Electrophysiologic procedures:** The initial electrophysiologic evaluation was performed with the patient in a fasting, nonsedated state after informed consent had been obtained. Digoxin, if required for congestive heart failure or atrial fibrillation, and propranolol, if required for angina, were continued. Digoxin dosage was adjusted to maintain the serum concentration between 0.8 and 2.0 ng/ml throughout the study period. Two to 4 quadripolar electrode catheters with a 1 cm interelectrode distance were inserted percutaneously through femoral and antecubital veins and positioned with fluoroscopic guidance at multiple intracardiac sites. Intracardiac electrograms were filtered below 30 and above 500 Hz and displayed simultaneously with scalar electrocardiographic leads I, II, and $V_1$ on a multichannel oscilloscope (Electronics for Medicine, VR-12). Data were stored on frequency-modulated magnetic tape (A-R Vetter, Rebersburg, Pennsylvania) and later retrieved on photographic paper at speeds of 75 to 200 mm/s.

Ventricular stimulation was performed with a programmable constant current stimulator (Medtronic 5325) that

delivered rectangular pulses of 2 ms duration. Ventricular stimulation was performed from 1 or more right ventricular sites at 4 to 5 times diastolic threshold (minimum 2 mA). The following stimulation protocol was used[4,5]: (1) atrial pacing at incremental rates of 100 to 300 beats/min; (2) premature atrial stimulation during atrial pacing at 1 or more basic cycle lengths; (3) ventricular pacing at incremental rates of 60 to 100 beats/min for 30 seconds; (4) premature ventricular stimulation with single ($S_2$) and double ($S_2$-$S_3$) extrastimuli during sinus rhythm and during fixed-rate ventricular pacing at multiple basic cycle lengths; (5) rapid ventricular pacing in brief bursts at rates of 100 to 280 beats/min: 3- to 5-beat pacing bursts were delivered at progressively shorter cycle lengths until 1:1 capture could no longer be achieved, sustained VT or VF occurred, or a paced rate of 280 beats/min was reached.

The same ventricular stimulation protocol was employed during both the initial study and during subsequent drug trials. The initiation of either sustained VT (>100 beats) or nonsustained VT (5 to 100 beats) was considered a significant response to stimulation.[4,5]

After the initial study, subsequent programmed stimulation trials were carried out using an indwelling bipolar electrode positioned at the right ventricular site from which VT had been initiated previously. Trials were conducted during steady-state quinidine therapy after serum concentrations of any previously used agent had dissipated. The mean total daily dose of quinidine base was 1,087 ± 204 mg with a range of 604 to 1,920 mg. Seventy-three patients received 3 or 4 divided doses/day of quinidine sulfate while 16 patients with gastrointestinal intolerance to quinidine sulfate received quinidine gluconate at similar intervals.

Quinidine therapy was evaluated during this in-hospital phase using 4 end points: (1) suppression of ability to initiate VT or VF by programmed ventricular stimulation; (2) initiation of VT or VF by programmed ventricular stimulation; (3) a clinical episode of spontaneous VT or VF before restudy with a simultaneous serum quinidine level of at least 2.0 μg/ml; or (4) intolerable early adverse effects. Patients who had an episode of symptomatic or sustained VT, cardiac arrest, or unexplained syncope during quinidine therapy were considered chronic treatment failures. During the first 24 to 48 hours of quinidine treatment, electrocardiographic rhythm strips were monitored and, if either marked Q-T prolongation (>+50% baseline), QRS widening (>+20% of baseline) or atrioventricular block was noted, quinidine was either discontinued or its dosage reduced.

Forty-nine patients received quinidine on only 1 dose schedule. The other 40 patients continued to manifest VT in response to ventricular stimulation during their initial trial with quinidine and were then begun on therapy at a higher dose. Thirty-one of these 40 patients underwent repeat programmed ventricular stimulation on the higher dose. The other 9 patients were unable to tolerate the higher dose because of adverse effects and were considered nonresponders to quinidine. All data presented represents that obtained during EP testing on the highest dosage of quinidine reached.

Quinidine was used in combination with a second antiarrhythmic agent only if both agents had been shown to be ineffective in preventing initiation of VT when each agent was used separately. Therapeutic trials involving quinidine in a combination with 1 or 2 other antiarrhythmic agents were performed in 35 patients.

Quinidine serum concentrations were determined at the time of electrophysiologic testing using fluorometric analysis after benzene extraction in a modification of the method of Cramer and Isaksson.[6,7] This method measures quinidine and dihydroquinidine and excludes polar metabolites.[7] The effects of quinidine in each individual patient were assessed using a $t$ test for matched pairs while comparisons between responders and nonresponders were made using a 1-tailed $t$ test for unmatched groups.

## Results

**Initial electrophysiologic studies:** In 86 patients, programmed cardiac stimulation initiated VT or VF during the initial study of antiarrhythmic drugs. Three patients had 1 or more spontaneous episodes of VT when attempts to withdraw therapy were made. The tachycardia rate was 237 ± 30 (mean ± standard deviation) beats/min. All episodes of VT or VF ended spontaneously or were interrupted without complication using either ventricular pacing or transthoracic, direct-current countershock.

**Ventricular stimulation during quinidine therapy (Table II):** Between 36 and 72 hours after the initiation of quinidine therapy, but before repeat EP testing was performed, 5 patients had a spontaneous episode of VT or VF. The serum quinidine concentration determined at that time was 2 to 3.2 μg/ml in these 5 patients. Three other patients developed adverse effects after the first several doses of quinidine. These adverse effects included fever, atrioventricular block, and severe hypotension, each of which occurred in 1 patient. These 8 patients did not undergo repeat programmed ventricular stimulation while taking quinidine.

In 30 of the remaining 81 patients, quinidine prevented the initiation of VT or VF by programmed ventricular stimulation. Sample electrocardiograms obtained in a patient who responded to quinidine are shown in Figure 1. In the 30 patients who responded to quinidine, the mean serum quinidine concentration at the time of testing was 2.9 ± 0.8 μg/ml.

In 51 patients of the 81 patients tested, quinidine failed to prevent the initiation of a ventricular ar-

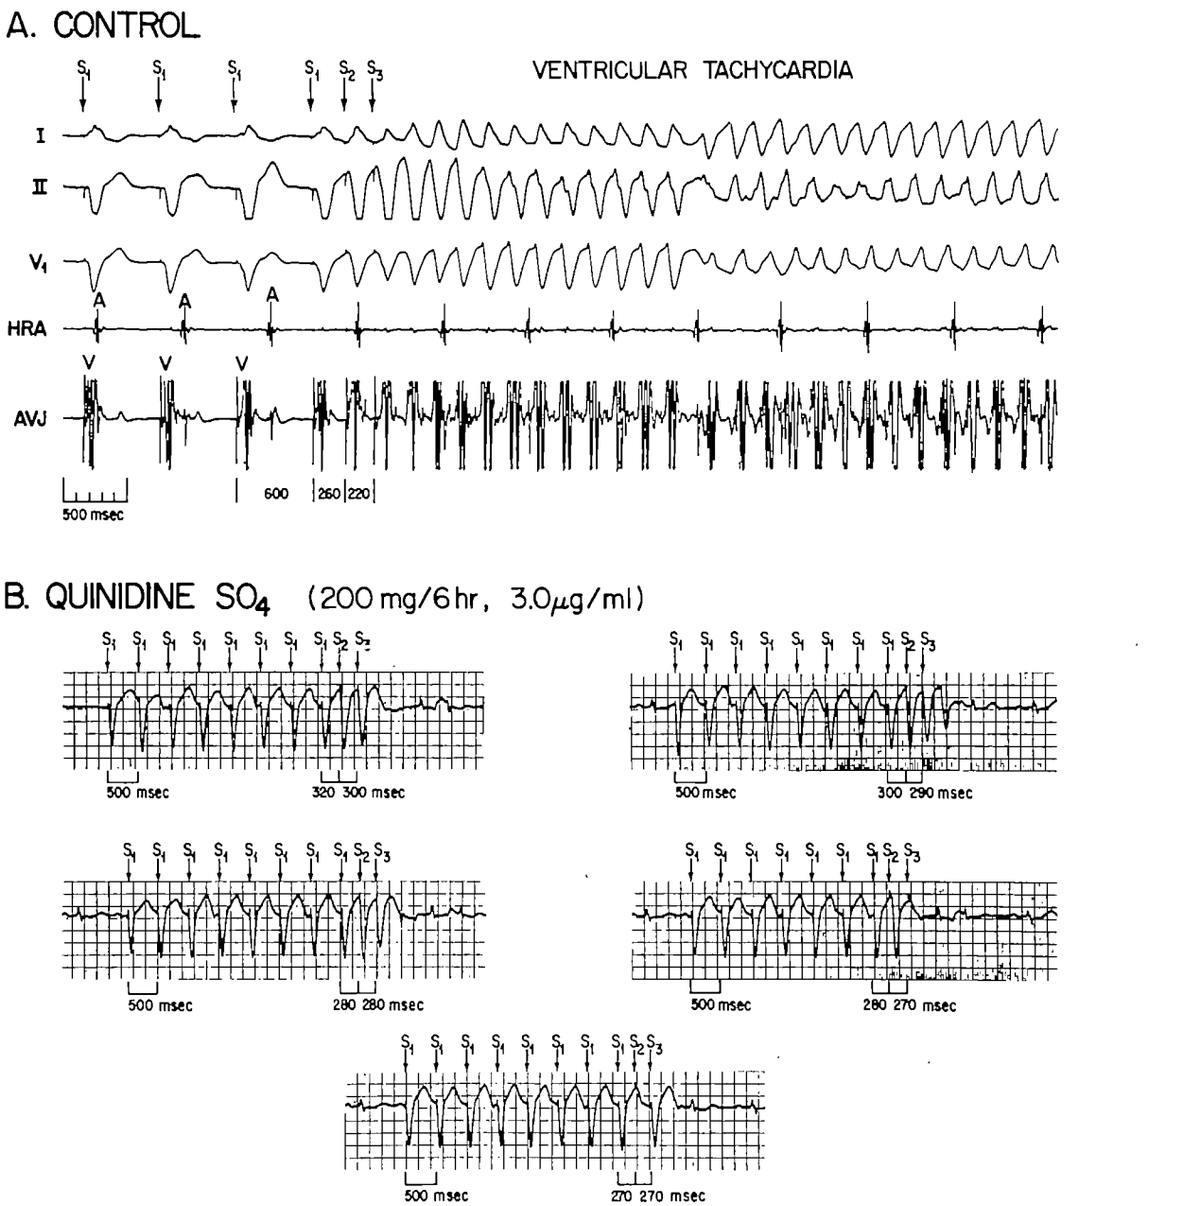

**FIGURE 1.** Response to quinidine in a patient with VT. **Panel A,** the tracings (**top to bottom**) represent surface electrocardiographic leads I, II, and $V_1$, and intracardiac recordings from the high right atrium (HRA) and the atrioventricular junction (AVJ). Two ventricular extrastimuli ($S_2$ and $S_3$) during fixed rate ventricular pacing at a cycle length ($S_1$-$S_1$) of 600 ms initiate sustained ventricular tachycardia. **Panel B,** all tracings represent surface electrocardiographic lead II. During quinidine therapy multiple attempts to initiate VT with double extrastimuli are unsuccessful and stimulation with shorter coupling intervals is impossible. Similar responses were noted to double extrastimuli at other basic cycle lengths and to bursts of rapid ventricular pacing (see Methods).

rhythmia by programmed ventricular stimulation. The mean serum concentration in the group of nonresponders was 2.8 ± 1.1 μg/ml and, as shown in Figure 2, the distribution of quinidine serum concentrations resembled that seen in those patients who responded to the drug. The effect of quinidine on the rate of induced VT observed is shown in Figure 3. Quinidine produced a modest decrease in the mean tachycardia rate from 222 ± 35 (mean ± standard deviation) to 196 ± 54 beats/min ($p < 0.001$). However, there was wide individual variation in the responses observed with changes of −120 to +60 beats/min noted in the rates of VT during therapy with quinidine. In 3 patients in whom a uniform morphology VT was initiated at the time of initial EP study, a more rapid polymorphic VT that degenerated rapidly to VF was observed during therapy with quinidine. In all 3 patients, serum quinidine concentrations were <3.0 μg/ml and none had markedly prolonged QRS durations or Q-Tc intervals (see Methods).

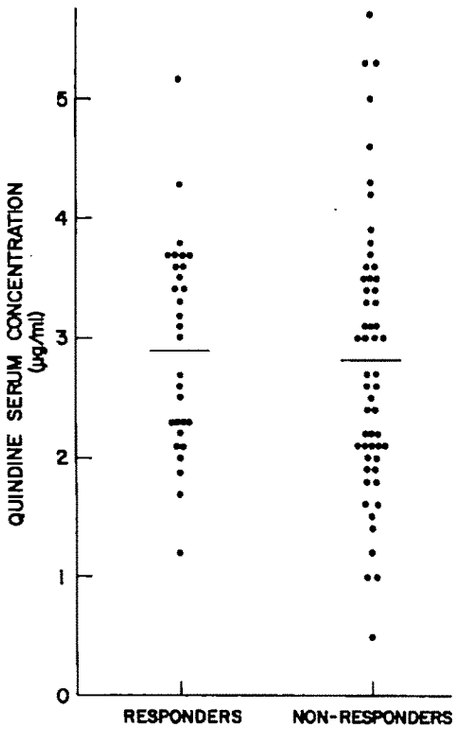

**FIGURE 2.** Quinidine serum concentrations in responders and nonresponders. **Each point** represents the serum concentration of quinidine in a patient at the time of repeat electrophysiologic study or failure before restudy. Only the highest concentration achieved is plotted for patients tested twice on different dosages.

**TABLE III Characteristics of Quinidine Responders and Nonresponders**

| | Responders (n = 30) | Nonresponders (n = 56) | p Value |
|---|---|---|---|
| LV ejection fraction (%)* | 53 ± 18 | 35 ± 17 | <0.002 |

| Quinidine dose† (mg day$^{-1}$) | 1,053 ± 309 | 1,104 ± 300 | NS |
| Quinidine serum concentration (μg/ml) | 2.9 ± 0.8 | 2.8 ± 1.1 | NS |

* Determined by either radionuclide angiography or contrast left ventriculography. † Expressed as quinidine base. Δ ERP RV = change in effective refractory period at the right ventricular stimulation site; NS = not significant. All values are mean ± standard deviation.

**TABLE IV Results of Chronic Therapy**

| | Responders | | Nonresponders* | |
|---|---|---|---|---|
| Response During EP Study | Quin Alone | Quin and 2nd AAD | Quin Alone | Quin and 2nd AAD |
| Alive and well | 25 | 7 | 1 | 3 |
| Late VT or VF | 2 | 1 | 1 | 5 |
| Late adverse effects | 3 | 0 | 0 | 0 |

* Nonresponders during electrophysiologic (EP) testing on an antiarrhythmic regimen using quinidine who were discharged on that regimen when no effective regimen could be identified. AAD = antiarrhythmic drug; Quin = quinidine.

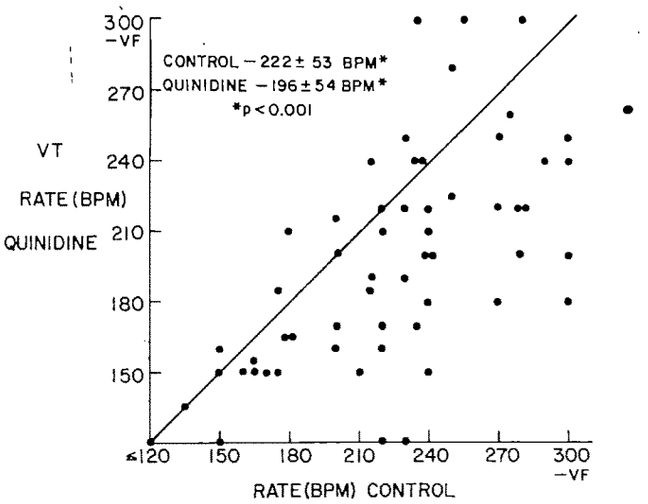

**FIGURE 3.** Effect of quinidine on VT rate. The **horizontal axis** represents the rate of VT observed at the initial study and the **vertical axis** represents the rate of the tachycardia during quinidine therapy. Although the usual effect was a decrease in tachycardia rate (points below the line of identity), in some patients acceleration was the observed effect (points above the line of identity).

Seven of the 31 patients (23%) tested at a second dosage level of quinidine responded to the increased dose. In all 7 the quinidine serum concentration had been ≤1.5 μg/ml (initial, 1.3 ± 0.2; final, 3.4 ± 0.9) at the time of the first trial. In the remaining 24 patients who underwent stimulation on 2 different dosage regimens, a higher serum concentration of quinidine at the second study (2.0 ± 0.5 versus 2.9 ± 1.1 μg/ml) did not increase drug efficacy. In the entire series there were 6 patients in whom serum concentrations ≥1.5 μg/ml could not be achieved without severe gastrointestinal adverse effects. This precluded higher dose therapy in these 6 patients and they are considered nonresponders.

**Combinations with other antiarrhythmic drugs:** Thirty-five patients who did not respond to quinidine alone were subsequently tested while receiving quinidine in combination with 1 or more antiarrhythmic drugs. Either mexiletine, propranolol, or amiodarone was the second drug used. Seven patients responded to a combination of quinidine and mexiletine and 1 patient's arrhythmia was suppressed with a combination of quinidine and propranolol during electrophysiologic testing.

**Characteristics of responders and nonresponders:** Table III compares the 30 patients who responded to quinidine alone with the 56 patients in whom quinidine therapy did not suppress spontaneous or stimulation-induced VT. The 3 patients with early adverse effects who did not undergo electrophysiologic testing while receiving quinidine are excluded. Quinidine produced a similar increase in the effective refractory period of the right ventricle in both groups. There was no significant difference between the 2 groups in either the dose of quinidine administered or the serum concen-

trations achieved. However, responders did have significantly higher left ventricular ejection fractions and were less likely to be receiving digitalis therapy than were nonresponders. Since in almost all cases digitalis therapy was used for the treatment of congestive heart failure, our data are insufficient to examine these 2 variables separately. However, serum digoxin levels were monitored during quinidine therapy; in only 1 case was a concentration >2.0 ng/ml detected.

**Results during chronic therapy (Table IV):** Chronic therapy with quinidine, either alone (30 patients) or in conjunction with a second antiarrhythmic drug (8 patients), was initiated in 38 patients whose arrhythmias were suppressed during programmed ventricular stimulation while receiving quinidine. The long-term results of this therapy are given in Table IV. Twenty-five of 30 patients receiving quinidine alone and 7 of 8 patients receiving quinidine in combination with another agent have remained free of VT, VF, or syncope during a mean follow-up of 24 ± 3 months. Three patients had adverse effects (severe diarrhea in 2 patients and fever in 1 patient) that necessitated discontinuation of quinidine therapy. Two patients receiving quinidine alone and 1 patient receiving quinidine in conjunction with mexiletine died suddenly during the follow-up period. These 3 deaths occurred 1, 3, and 12 weeks after hospital discharge. One of these 3 patients had stable but severe left ventricular dysfunction and the other 2 had severe angina and were awaiting coronary artery bypass surgery.

Ten patients whose inducible arrhythmias were not fully suppressed on any medical regimen tested were discharged on quinidine therapy. Eight received quinidine in combination with other agents while 2 received quinidine alone. Six of these 10 patients (60%) have had a recurrent symptomatic episode of VT or VF during the follow-up period.

If patients with adverse effects during chronic therapy are excluded, the results of programmed cardiac stimulation are seen to be highly predictive of long-term efficacy. When quinidine prevented the initiation of VT or VF during electrophysiologic testing, it subsequently proved effective during chronic therapy in 32 of 35 patients. In contrast, when quinidine therapy was predicted by electrophysiologic testing to be ineffective, only 4 of 10 patients remained free of symptomatic arrhythmia. The difference between these groups is highly significant ($p < 0.002$ by Fisher's test).

## Discussion

An evaluation of the acute phase efficacy of any form of antiarrhythmic therapy requires a reproducible end point that bears a direct relation to the goal of therapy. The suppression of the ability to initiate VT by means of programmed ventricular stimulation has been shown previously to predict future protection from recurrent ventricular arrhythmias.[5,8,9] In this study, serial electrophysiologic testing was employed to assess the efficacy of quinidine in the treatment of selected patients with serious ventricular arrhythmias. Our results demonstrate that 30 of 89 (34%) patients with VT at their initial electrophysiologic study failed to manifest any ventricular arrhythmia in response to programmed ventricular stimulation while receiving quinidine. In an additional 8 patients, full suppression was achieved when quinidine was used in combination with a second antiarrhythmic agent. Thus, on the basis of acute electrophysiologic testing, quinidine was predicted to provide or contribute to long-term protection from recurrent VT or VF in 38 of 89 (43%) consecutive patients in whom it was tested. Over a mean of 24 months clinical follow-up, 32 of these 38 (84%) patients were successfully treated, while failures occurred in 3 (7.9%) patients with intolerable adverse effects and 3 (7.9%) with recurrent arrhythmias.

Two previous series involving the use of programmed ventricular stimulation in patients with ventricular arrhythmias have included a group of patients studied while receiving quinidine. Horowitz et al[8] reported quinidine effective in 1 of 12 patients, while Mason and Winkle[9] reported that 5 of 14 patients (36%) responded favorably to the drug. Details correlating drug levels with efficacy are unavailable from these reports and some patients received only a single loading intravenous infusion before repeat programmed ventricular stimulation was performed. Several other studies have reported quinidine's efficacy in suppressing either spontaneous or exercise-induced ventricular ectopic activity. In 2 separate reports, Lown et al[10,11] reported that short-term administration of quinidine was effective in 7 of 23 and 10 of 18 patients with frequent or complex ventricular premature beats, respectively, for a combined success rate of 41% (17 of 41 patients). Gey et al,[12] using a single oral loading dose, found that quinidine was "partially or totally successful" in 9 of 19 patients with ventricular ectopic activity during exercise testing. Winkle et al[13] examined the effects of quinidine on ventricular ectopy and found quinidine to be effective in 8 of 13 patients during ambulatory monitoring and in 6 of 10 patients during exercise testing. However, as discussed by Winkle,[14] there are problems in the assessment of antiarrhythmic drug efficacy using such techniques due to the low reproducibility of arrhythmia on successive recordings during serial exercise or ambulatory monitoring periods. This factor limits the practical utility of the estimates made in the studies cited above. Responses to programmed ventricular stimulation during serial drug testing are highly reproducible,[15] and drug effects may be reliably assessed using this form of testing. In this series, when electrophysiologic techniques were used in a large group of patients, the efficacy rate of quinidine was comparable to that reported with other techniques[8–12] and the data obtained accurately predicted the outcome of chronic therapy.

The quinidine serum concentrations required to produce suppression of VT during repeat ventricular stimulation ranged from 1.2 to 5.1 μg/ml (2.9 ± 0.8, mean ± standard deviation). Ninety percent of the values were between 1.5 and 4.0 μg/ml, and all but 1 of the patients treated successfully during chronic follow-up were within this range. The fluorometric assay employed in this study yields results comparable to highly specific chromatographic techniques.[7,16] Thus,

these data may be used to define an approximate "therapeutic range" for quinidine in patients with VT or VF unassociated with acute myocardial infarction. However, if a less specific assay which includes other quinidine metabolites, such as the protein precipitation method of Brodie et al[17] or a less selective extraction procedure is employed, a higher range would have to be established for that particular laboratory. Previous investigators using a variety of criteria for antiarrhythmic efficacy reported similar mean levels in their patient groups with either atrial[18,19] or ventricular[20–22] arrhythmias; at least 2 reports observed that serum levels seen in responders and nonresponders were comparable.[21,22] These data confirm that antiarrhythmic drug therapy must be individualized for each patient. The success rate of only 30 to 40% observed in this series should serve to caution physicians initiating antiarrhythmic therapy with quinidine to define carefully criteria for efficacy and to anticipate that only a minority of individual patient trials are likely to be successful.

Recently, Engel et al[23] and Greenspan et al[24] reported that high dose procainamide therapy may achieve control of ventricular arrhythmias resistant to traditional therapy with that drug. Acute toxicity was not markedly increased. During therapy with quinidine, however, gastrointestinal side effects may become more prominent with even modest increases in dosage and added benefits from high dose programs may be difficult to achieve. However, there may be some patients able to tolerate such therapy in whom arrhythmia suppression can be maintained without toxicity.

The results of this study do not allow us to predict with certainty which patients with ventricular arrhythmias will respond to quinidine. Patients with congestive heart failure seem less likely to respond. This may be related to the concurrent use of digoxin in these patients even though serum digoxin concentrations were within the accepted therapeutic range. At the concentrations employed in this series of patients, quinidine has not been shown to affect myocardial contractility adversely.[25] The presence of heart failure, however, is a frequently noted determinant of an adverse prognosis in patients with ventricular arrhythmias[26–28]; it is possible that the electrophysiologic abnormalities in patients with ventricular dysfunction are more resistant to any pharmacologic therapy. Other factors may also affect the results of antiarrhythmic therapy. In this series, 2 patients without signs of congestive heart failure experienced a fatal arrhythmia in the setting of unstable angina pectoris despite arrhythmia suppression during acute electrophysiologic testing. These observations emphasize the fact that the severity of the underlying cardiac disease remains a critical determinant of both acute and chronic responses to therapy for ventricular arrhythmias and effective therapy must always be directed at multiple factors.

Prescription of antiarrhythmic therapy requires the use of appropriate criteria to predict long-term antiarrhythmic efficacy. The correlation demonstrated in this study between responses during electrophysiologic testing and clinical efficacy during long-term follow-up confirms the value of such studies in the prescription of prophylactic antiarrhythmic drug therapy with quinidine. When its use is guided by these techniques, quinidine remains a useful agent for long-term prophylaxis in selected patients with recurrent, life-threatening ventricular arrhythmias.

# Enhanced Parasympathetic Tone Shortens Atrial Refractoriness in Man

ERIC N. PRYSTOWSKY, MD, GERALD V. NACCARELLI, MD, WARREN M. JACKMAN, MD, ROBERT L. RINKENBERGER, MD, JAMES J. HEGER, MD, and DOUGLAS P. ZIPES, MD

**The purpose of this study was to determine the effects of enhanced vagal tone on human right atrial refractoriness in 12 patients. A specially built neck collar connected to a vacuum source was placed around the patient's neck and enhanced vagal tone was produced during neck suction using intracollar negative pressures of 50 to 60 mm Hg. Refractory periods were determined with a catheter electrode positioned in the high right atrium near the sinus node. Induced neck suction increased the spontaneous sinus cycle length from 837 ± 96 to 1,136 ± 273 ms ($p < 0.001$) and shortened the atrial effective refractory period from 241 ± 24 to 230 ± 20 ms ($p < 0.01$) and the atrial functional refractory period from 272 ± 32 to 262 ± 29 ms ($p < 0.01$). In 2 of 2 patients, collar-induced decreases in atrial refractoriness and increases in spontaneous cycle length were prevented after atropine (0.03 mg/kg) was given intravenously. It is concluded that enhanced vagal tone mediated through muscarinic receptors shortens atrial refractory periods in man.**

Vagal stimulation or the addition of acetylcholine[1–3] shortens atrial refractoriness, action potential duration, or both in rabbit, cat, and dog atria. Further, recent in vitro data[4] in normal human atrial tissue obtained at surgery demonstrate that ouabain shortens the action potential duration, an effect prevented by atropine. This observation suggests that the primary effect of ouabain was mediated through muscarinic receptors.

Because it is difficult to increase vagal tone in vivo without stimulating the vagal nerves directly, studies in patients to evaluate the effects of heightened vagal tone on atrial refractoriness have relied on indirect approaches such as inhibiting vagal tone with atropine or increasing vagal tone with ouabain. In conflict with the aforementioned data obtained during in vitro experiments or during in vivo animal experiments, Dhingra et al demonstrated in man that atropine shortened[5] and ouabain prolonged[6] atrial refractoriness. Interpretation of these results suggests that heightened vagotonia *prolongs* atrial refractoriness in man, a conclusion discordant with the previous data. However, in neither of these studies was the sympathetic nervous system blocked, and the results may have been due in part to the complex interactions of the parasympathetic and sympathetic nervous systems on the heart.[7–9] For example, acetycholine, by activating muscarinic receptors, can cause presynaptic inhibition of norepinephrine release from adrenergic nerves.[9] Atropine might remove vagal inhibition of sympathetic nerves and result in shortened atrial refractoriness due to a relative increase in adrenergic tone.[10] Likewise, ouabain, by increasing the effects of vagal tone on adrenergic nerves or by exerting an antisympathetic effect,[11] might prolong atrial refractoriness. The only certain way to determine the effects of cholinergic stimulation on atrial refractoriness is to increase vagal tone selectively.

Eckberg et al[12] developed a lead collar that can be placed around a patient's neck and through which

negative pressures can be generated by vacuum suction. Intracollar negative pressure activates the carotid baroreflex and, during the first few seconds of suction, selectively increases vagal tone. Atropine but not propranolol blocks this response.[13,14] The purpose of this study was to investigate the effects on human atrial refractoriness of increased vagal tone induced by neck collar suction.

## Methods

Twelve patients undergoing electrophysiologic study for symptomatic atrioventricular block, ventricular tachyarrhythmias, syncope, or a combination of these (Table I) had atrial refractory periods determined before and during neck collar suction. No patient had a history of sinus nodal dysfunction, atrial arrhythmias, or electrocardiographic or echocardiographic evidence of atrial abnormalities. All had normal sinus nodal function on electrophysiologic testing. All patients were studied in the postabsorptive state and no patient was given sedatives before or during the time of study. No patient had been taking digitalis and all cardioactive medicines were discontinued 48 to 72 hours before the electrophysiologic procedure.

Two to 4 multipolar electrode catheters were inserted intravenously, using percutaneous technique, and positioned in multiple areas in the heart. Local anesthesia was obtained using a minimal amount[15] of 1% xylocaine. Atrial pacing was performed with a quadripolar catheter advanced to the heart from the right femoral vein. The interelectrode distance was 10 mm; the distal electrode pair was used for pacing and the proximal pair for recording atrial electrograms. In 11 of 12 patients, the distal electrode pair of the catheter used to determine atrial refractoriness was positioned near the area of the sinus node in the high right atrium at the junction of the atrium and superior vena cava, an area shown to have substantial parasympathetic innervation.[3,16,17] A stable catheter position near the sinus node could not be obtained for Patient 5 and the catheter was positioned in the high medial right atrium near the septum. A programmable stimulator (Medtronic 5325) delivered square wave stimuli 1.8 ms duration and twice late diastolic threshold. Data from multiple surface and intracardiac leads were displayed on a multichannel oscilloscopic recorder (Electronics for Medicine VR 12) and directly written out on photographic paper at 100 mm/s. Signals from the electrocardiographic surface leads were filtered at 0.1 to 20 Hz and from the intracardiac leads at 30 to 500 Hz.

**Enhanced vagal tone:** To assess the effects of reflex vagal stimulation (enhanced vagal tone) on atrial refractoriness and sinus nodal automaticity, a specially built neck suction device was used.[12] This device was constructed from lead stock and can be molded to fit subjects with different cervical anatomy. One line from the neck chamber connects to a vacuum source and one connects to a pressure gauge. The chamber was placed around the patient's neck and the degree of suction from the vacuum source was adjusted to produce neck suction at intracollar negative pressures of 50 to 60 mm Hg.

The vacuum source was turned on and kept at a constant level throughout the study but not connected to the patient. The patients were instructed to keep their mouths open during neck suction to prevent an inadvertent Valsalva maneuver. Intracollar negative pressure was obtained by manually opening a valve that connected the vacuum source to the neck collar; steady-state intracollar negative pressure occurred within 1 second after the valve was opened. The valve was then closed to remove intracollar negative pressure. Durations of neck suction were 2 seconds for sinus nodal testing and 2 to 3 seconds for atrial refractory period testing. It is important to note that previous data obtained by us[14] and others[13] demonstrate that during the first 3 seconds of neck suction increased vagal tone but not sympathetic withdrawal occur due to carotid baroreflex activation.

**TABLE I Patient Characteristics**

| Patient | Age (yr) & Sex | Cardiovascular Disease | Clinical Arrhythmias |
|---|---|---|---|
| 1 | 58M | PED | RMVT[23] |
| 2 | 51M | CAD | Nonsustained VT |
| 3 | 41F | MVP | Nonsustained VT |
| 4 | 65M | PED | Sustained VT |
| 5 | 33M | PED | Type I AV block |
| 6 | 15M | PED | Type I AV block |
| 7 | 52F | CAD | RBBB, LAFB |
| 8 | 52M | CM | VT/VF |
| 9 | 40M | CM | Nonsustained VT |
| 10 | 44F | PED | Syncope |
| 11 | 61F | PED | RMVT |
| 12 | 42M | CM | Nonsustained VT |

AV = atrioventricular; CAD = coronary artery disease; CM = idiopathic cardiomyopathy; LAFB = left anterior fascicular block; MVP = mitral valve prolapse; PED = primary electrical disease; RBBB = right bundle branch block; RMVT = repetitive monomorphic ventricular tachycardia; VF = ventricular fibrillation; VT = ventricular tachycardia.

The effect of intracollar negative pressure, induced for 2 seconds, on spontaneous sinus cycle length was obtained 3 times in each patient before atrial pacing. Then, atrial refractoriness was determined before and during neck suction by the following technique. The atria were paced at a constant cycle length ($S_1$-$S_1$) throughout refractory period testing and the drive train was not interrupted even after induced premature stimuli.[18] Thus, changes in heart rate that can affect refractoriness were avoided. After 30 seconds of pacing, premature stimuli ($S_2$) were induced after every eighth paced complex beginning with an $S_1$-$S_2$ interval initially too short to result in atrial depolarization. The $S_1$-$S_2$ interval was increased by 5 ms increments until $S_2$ produced an atrial response. The $S_1$-$S_2$ interval was increased further until the shortest $A_1$-$A_2$ interval was determined. Then, the effects of enhanced vagal tone on atrial refractoriness were evaluated. The $S_1$-$S_2$ interval was set at the longest premature interval at which $S_2$ tested 3 times did not result in an atrial depolarization. This $S_1$-$S_2$ interval was tested a fourth time, but 2 to 3 seconds before $S_2$ intracollar negative pressure was activated. If $S_2$ resulted in atrial depolarization during neck suction, the same $S_1$-$S_2$ interval was tested 3 additional times without induced neck suction to make sure that atrial capture during neck suction was not due to a change in the baseline atrial refractoriness. The premature coupling interval was decreased by 5 ms and tested 3 times before neck suction, during neck suction, and again 3 times after neck suction. This procedure was repeated at 5 ms $S_1$-$S_2$ decrements until an $S_1$-$S_2$ interval occurred that did not result in atrial depolarization on 3 attempts before and during induced neck suction. Thus, each $S_1$-$S_2$ interval was tested 6 times without neck suction and at least once with neck suction.

The control atrial effective refractory period was the longest $S_1$-$S_2$ interval at which $S_2$ consistently resulted in no atrial depolarization during the 6 times it was tested without neck suction. Atrial effective refractory period during neck suction was the longest $S_1$-$S_2$ interval at which $S_2$ on 3 consecutive attempts did not result in atrial depolarization. The atrial functional refractory period was defined as the shortest ob-

tainable $A_1$-$A_2$ interval during control or enhanced vagal tone. The paired $t$ test was used to analyze changes in sinus cycle length and atrial refractoriness before and after neck suction, and the data are reported as mean ±1 standard deviation.

## Results

During induced intracollar negative pressure, enhanced vagal tone prolonged the spontaneous sinus cycle length; for each patient the longest P-P interval obtained is shown in Table I. The maximum increase in P-P interval always was observed during the first 2 seconds of induced neck suction. For all patients except Patients 6, 7, and 10, spontaneous cycle length increased more than 20%, and the group cycle length was prolonged from 837 ± 96 to 1136 ± 273 ms (36%).

Enhanced vagal tone shortened atrial effective and functional refractory periods in 9 of 12 patients; in no patient was refractoriness increased (Table II, Fig. 1). For all patients, atrial effective refractory period was 241 ± 24 ms before and 230 ± 20 ms during induced intracollar negative pressure ($p < 0.01$). Atrial functional refractory period shortened during neck suction from 272 ± 32 to 262 ± 29 ms ($p < 0.01$). Atrial refractoriness did not change in Patients 5, 6, and 7. Patients 6 and 7 also had minimal increases in spontaneous cycle length during induced neck suction. Patient 5 was the only patient whose atrial pacing site was not near the area of the sinoatrial node.

Two patients received atropine intravenously (0.03 mg/kg) (Elkins-Sinn) and atrial refractoriness was retested using the same pacing cycle length. During atropine administration, induced intracollar negative pressure did not decrease refractoriness as it did in the control state. Furthermore, after atropine, neck suction had no effect on spontaneous cycle length.

## Discussion

This study demonstrates that atrial effective and functional refractory periods decrease in man during enhanced vagal tone, and supports previously published data in animals and in vitro data from human atria. To augment parasympathetic tone, we used a specially designed neck suction device.[12] Using this device, Eckberg et al[19] showed that during neck suction the first significant decrease in systolic arterial blood pressure occurred at 3 seconds and diastolic pressure fell at 2 seconds. During atrial pacing, we measured intraarterial

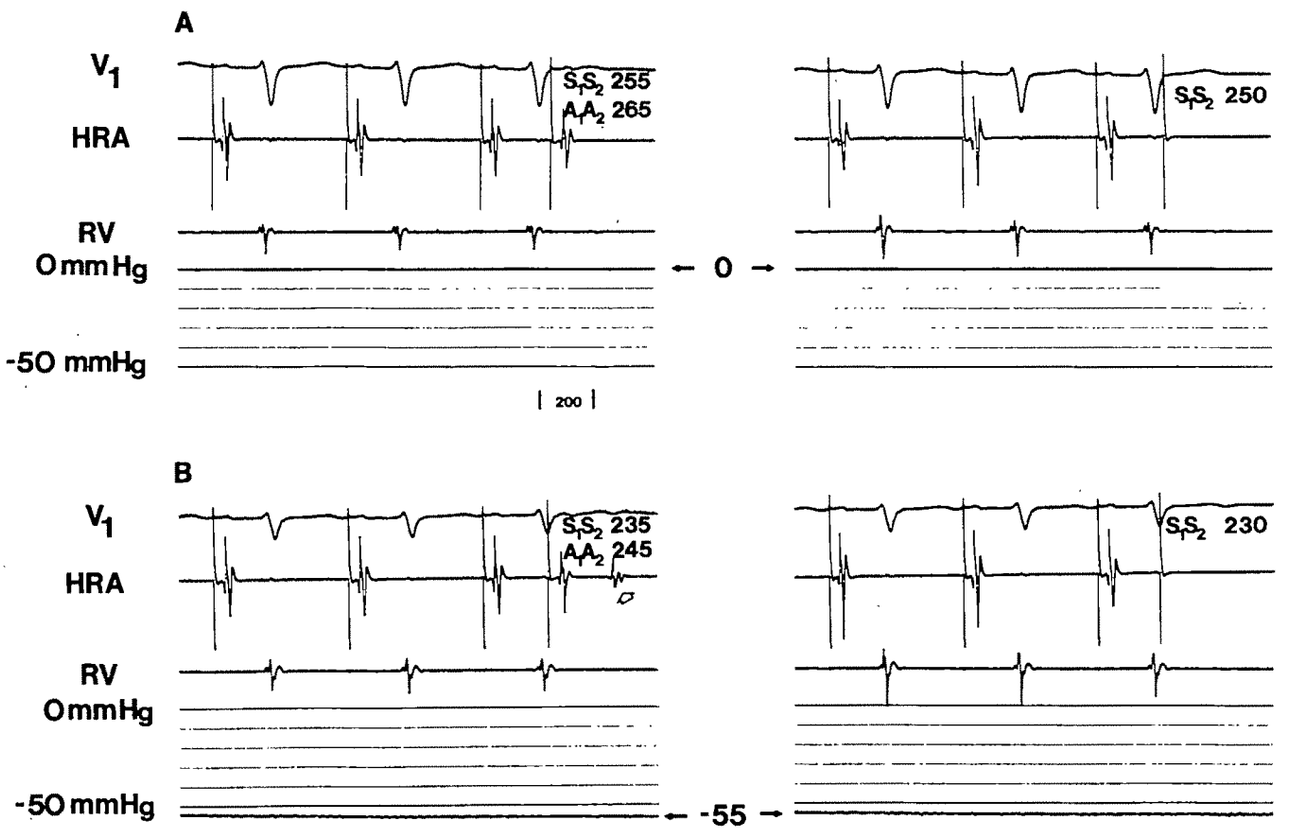

**FIGURE 1.** Change in atrial refractoriness during enhanced vagal tone. Atrial refractory period determinations were made before (**A**) and during (**B**) induced neck suction. Atrial effective and functional refractory periods were 250 and 265 ms, respectively, and shortened during neck suction (−55 mm Hg) to 230 and 245 ms, respectively. Note the repetitive atrial response (**arrow**) induced during neck suction. For all panels, the upper 3 recordings are standard electrocardiographic lead $V_1$ and intracardiac electrograms from the high right atrium (HRA) and right ventricle (RV). Intracollar pressure is noted on the bottom of the panels by the **heavy black line.**

ERP = effective refractory period; EVT = enhanced vagal tone; FRP = functional refractory period; PCL = pacing cycle length; SD = standard deviation.

pressure in 2 patients through a cannula connected to a strain gauge pressure transducer; our results agreed with those of Eckberg et al.[19] Since it takes several seconds after hypotension for reflex autonomic changes to affect cardiac function,[20] the changes in atrial refractoriness induced during 2 to 3 seconds of neck suction did not result from an increase in reflex sympathetic tone. Additionally, previous data[13,14] demonstrate that atropine, but not propranolol, blocks the prolonged P-P interval that occurs during the first few seconds of induced neck suction.

Two additional observations indicate that the changes observed during neck suction were caused by increased vagal tone. First, neck suction caused no change in heart rate or atrial refractoriness in 2 of 2 patients after atropine was administered. Second, if enhanced reflex sympathetic tone, rather than parasympathetic tone, shortened atrial refractoriness during neck suction for ≤3 seconds, one would expect atrial refractoriness to shorten during more prolonged neck suction because of the time course of the sympathetic response. However, when neck suction was initiated 5 seconds before the premature atrial complex, atrial refractoriness usually did not change from control values. The inability to shorten atrial refractoriness during prolonged neck suction is more consistent with a cholinergic rather than an adrenergic response. Vagal tone during neck suction progressively decreases over time. The decrease in enhanced vagal tone during prolonged neck suction is consistent with the observation of Eckberg et al,[21] who showed that neck suction produced an initial decrease in heart rate that gradually returned to control values within 5 seconds.

The failure of enhanced vagal tone to shorten atrial refractoriness in Patient 5 may relate to the medial right atrial pacing site tested. Parasympathetic nerve terminals predominate in the area around the sinus node,[17] and Zipes et al[3] showed in the dog that vagal stimulation shortened atrial refractoriness at the sinus nodal area more than at any other atrial site. Since neck suction produced enhanced vagal tone in Patient 5, as demonstrated by a significant decrease in heart rate, it is reasonable to postulate that the inability of enhanced vagal tone to shorten atrial refractoriness in this patient may have occurred because the atrial site tested had relatively little parasympathetic innervation.

The differences between our results and the results obtained using atropine[5] may be explained in part by the complex interactions on the heart exerted by the parasympathetic and sympathetic nervous systems.[7–9] In particular, acetylcholine, by activation of muscarinic receptors, can cause presynaptic inhibition of release of norepinephrine from adrenergic nerves.[9] Since isoproterenol shortens human atrial refractoriness (unpublished results), the effect of atropine administration may depend on the baseline level of adrenergic and vagal tone, and on the amount of presynaptic vagal inhibition. If both substantial presynaptic inhibition and sympathetic tone are present, the overall effect of atropine might be to shorten atrial refractoriness. If minimal presynaptic inhibition and sympathetic tone are present, atropine might lengthen atrial refractoriness by reversing the direct (postsynaptic) effect of acetylcholine on atrial tissue. Of note, in the 2 patients given atropine, atrial refractoriness increased in 1 and decreased in the other.

Three patients demonstrated repetitive atrial responses to a single induced premature atrial complex, and repetitive atrial responses occurred only during enhanced vagal tone (Fig. 1). Induction of atrial fibrillation during atrial refractory period determination in man often is preceded by repetitive atrial responses, although atrial fibrillation did not occur in these patients. This potential arrhythmogenic consequence of enhanced vagal tone in man agrees with the well-known effect of heightened parasympathetic tone in facilitating atrial arrhythmias in animals. Alternatively, the induced repetitive atrial complexes in our patients may result from the shortened atrial functional refractory period.[22]

# Effect of Local Lidocaine Anesthesia on Ventricular Escape Intervals During Permanent Pacemaker Implantation In Patients With Complete Heart Block

BERNARD D. KOSOWSKY, MD, SHAHID I. MUFTI, MD, GURINDER S. GREWAL, MD, RICHARD H. S. MOON, MD, W. LINDA CASHIN, MD, JOHN O. PASTORE, MD, and K. RAMASWAMY, MD

**Transient asystole is often noted during the course of permanent pacemaker implantation in patients with complete heart block. Since subcutaneous lidocaine is frequently used as the local anesthetic agent for permanent pacemaker implantation, the effect of this drug on ventricular escape intervals was studied. Ventricular escape intervals after transient cessation of pacing were studied in 9 patients with complete heart block before and 10, 30, and 45 minutes after subcutaneous lidocaine administration for permanent pacemaker implantation. The total lidocaine dose ranged from 170 to 400 mg (1.9 to 9.5 mg/kg of body weight). Therapeutic blood levels were achieved in 7 patients. The mean ventricular escape interval before lidocaine was 1.83 ± 0.32 seconds, which increased to 2.58 ± 1.24, 2.96 ± 1.06, and 2.68 ± 1.27 seconds at 10, 30, and 45 minutes after lidocaine ($p < 0.02$). The mean maximal escape interval before lidocaine was 2.06 ± 0.30 seconds, which increased to 3.80 ± 1.44 seconds ($p < 0.01$), a mean increase of 84%. The percent increase in maximal escape interval was related directly to the peak lidocaine level achieved. After lidocaine administration, 5 patients had asystole >4 seconds and 1 required resumption of pacing.**

**Thus, subcutaneous lidocaine contributes to the occurrence of asystole seen during permanent pacemaker implantation. It is advisable to limit the amount of lidocaine administered during permanent pacemaker implantation to the minimum necessary to achieve adequate local anesthesia. Strong consideration should be given to the use of a temporary pacemaker in patients with complete heart block during permanent pacemaker implantation even in the absence of previous asystole.**

Transient asystole is often noted during the course of permanent pacemaker implantation in patients with complete heart block. Asystole may occur when temporary pacing is momentarily halted for the measurement of pacing or sensing thresholds, even in patients who did not demonstrate pacer dependency before the procedure.

Subcutaneous lidocaine is frequently used as the anesthetic agent for permanent pacemaker implantation, and therapeutic blood concentrations of lidocaine have been demonstrated in patients in whom this agent is used for local anesthesia.[1] To assess whether lidocaine is responsible for the occurrence of asystole during pacemaker implantations, we studied the effects of the subcutaneous use of this drug upon serum lidocaine levels and ventricular escape intervals after transient cessation of pacing in patients with complete heart block.

## Methods

The 9 patients, aged 57 to 83 years (mean 76), had complete heart block and permanent pacemakers implanted. Three patients had narrow QRS complexes of ≤0.08 second duration on a 12-lead electrocardiogram, whereas in 6 the complexes were widened. Of these, 4 had a right bundle branch pattern and 2 had a nonspecific intraventricular conduction delay. Eight patients had a history of syncope or near-syncope. None had abnormalities of liver function.

* Patient had pulse generator replacement only. † $p < 0.01$. ‡ $p < 0.02$. P = required resumption of ventricular pacing.

Eight patients were receiving their first pacemaker and each had a temporary pacemaker in place before the procedure. In 7 of these cases, the temporary pacer was inserted more than 24 hours before the study. One patient underwent pulse generator replacement and did not have a temporary unit.

In each patient, a constant physiologic pacing rate was maintained by means of the previously placed temporary or permanent pacemaker. An indwelling catheter was inserted into an arm vein to obtain serum lidocaine levels.

After the patient was appropriately prepared and draped, a baseline serum lidocaine level was drawn. Pacing was then transiently stopped and ventricular escape intervals were recorded. Cessation of pacing was accomplished by abruptly turning off the temporary pacemaker or by inhibiting the previously implanted permanent pacemaker by means of an externally applied pulsating electromagnet. Pacing was immediately resumed if a patient demonstrated presyncopal symptoms or other untoward effects. Under no circumstance was a patient allowed to have a pause of greater than approximately 6 seconds. Measurements were repeated 3 to 6 times in each patient, with approximately 1 minute of pacing between determinations. Recordings were made on a standard electrocardiograph at paper speeds of 25 and 50 mm/s.

After baseline determinations, the surgeon began the implantation procedure by infiltrating 1% lidocaine solution into the subcutaneous tissues of the deltopectoral region, being careful to avoid intravascular injection. The surgeon was instructed to employ standard operating techniques and to use as much lidocaine as was deemed necessary to attain adequate local anesthesia.

Serum lidocaine levels were drawn and escape intervals were measured 10, 30, and 45 minutes after the injection of lidocaine. In each patient, the number of determinations of escape intervals at each juncture was the same as that obtained in the control period. In 1 patient no data were obtained at 45 minutes.

Lidocaine levels were determined by the EMIT homogeneous enzyme immunoassay method.[2] Standard statistical techniques were utilized. A two-way analysis of variance was performed to compare escape intervals before and after lidocaine injection.

## Results

A summary of the data from each patient is given in Table I. The dose of lidocaine used ranged from 170 to 400 mg (mean 307) or 1.9 to 9.5 mg/kg of body weight (weight not available in 1 patient). The peak serum lidocaine levels ranged from 0.3 to 2.2 μg/ml and occurred either 30 or 45 minutes after injection. Therapeutic lidocaine levels of 1.1 to 2.4 μg/ml were achieved in 7 of the 9 patients. One of the patients (Patient 5) with a less than therapeutic level had a pulse generator replacement only.

Serum lidocaine levels and mean ventricular escape intervals before and 10, 30, and 45 minutes after lidocaine injection are shown in Table I. The mean ventricular escape interval in the control period was 1.83 ± 0.32 seconds. This increased to 2.58 ± 1.24, 2.96 ± 1.06, and 2.68 ± 1.27 seconds at 10, 30, and 45 minutes after lidocaine administration ($p < 0.02$, comparing each period with baseline). The mean escape intervals at 30 and 45 minutes were greater than the baseline values in every case. A representative example of escape interval prolongation is seen in Figure 1. Based on QRS morphology, 6 patients displayed a single escape focus

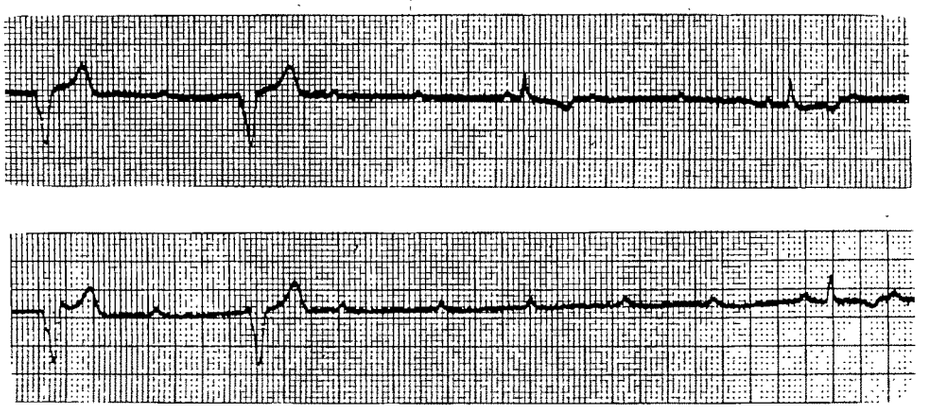

**FIGURE 1.** A representative lead II electrocardiographic tracing in Patient 4 demonstrating the effects of temporary cessation of pacing before (**top**) and after (**bottom**) lidocaine administration. The first 2 beats in both tracings are paced beats by way of bipolar temporary pacemaker. Paper speed is 25 mm/s.

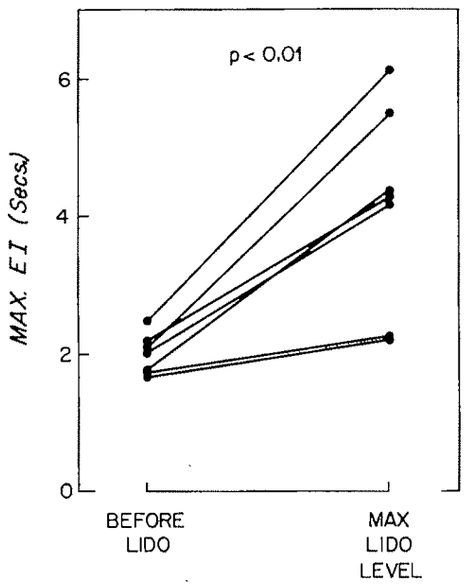

**FIGURE 2.** Maximal escape intervals (MAX EI) in 7 patients who achieved therapeutic lidocaine levels before lidocaine administration (BEFORE LIDO) and at maximal lidocaine level (MAX LIDO LEVEL).

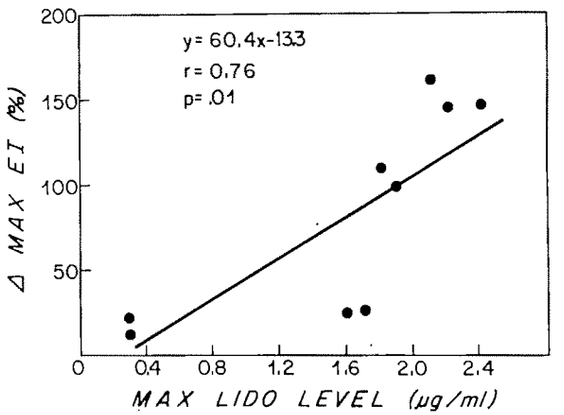

**FIGURE 3.** Relation between the change in maximal escape interval (Δ MAX EI) at the time of maximal lidocaine level (expressed as percent increase over control) and the serum lidocaine level at that time (MAX LIDO LEVEL).

during baseline studies and 3 patients had 2 foci. In only 1 instance did a patient have an escape focus after lidocaine injection which was not evident in the baseline. All patients with narrow QRS complexes on the initial electrocardiogram had escape foci whose QRS intervals were ≤0.09 second. Electrophysiologic studies were not performed to better identify the location of the escape foci.

The maximal ventricular escape intervals for each patient during the control period and at the time of maximal serum lidocaine levels are shown in Table I. These same values for the 7 patients who achieved therapeutic lidocaine levels are displayed in Figure 2. The mean maximal escape interval before lidocaine administration was 2.06 ± 0.30 seconds. At the time of peak lidocaine level, this increased to 3.80 ± 1.44 seconds ($p < 0.01$), a mean increase of 84%. In 6 of the 7 patients who achieved therapeutic drug levels, the longest escape interval observed occurred at the time of maximal lidocaine level. The degree of escape interval prolongation was directly related to the height of the serum lidocaine level. Figure 3 displays the percent increase in escape interval at peak lidocaine level as related to the drug level at that time. The correlation coefficient is 0.76 ($p = 0.01$). In the control period, no patient had asystole for longer than 2.56 seconds, and it was not necessary to turn the pacer back on in any patient. After lidocaine administration, 5 patients had asystole for >4 seconds and 1 required resumption of pacing after presyncopal symptoms or >6 seconds of asystole.

## Discussion

We have frequently observed asystole after transient cessation of pacing during a permanent endocardial pacemaker implantation procedure. This phenomenon generally occurs during the course of determining pacing and sensing thresholds. The occurrence of asystole may preclude the measurement or recording of the patient's intrinsic intracardiac QRS signal, thereby making it impossible to assess the sensing function of

a demand pacemaker. Furthermore, asystole may compromise the ability of the operator to reposition the electrode if there is no other means of maintaining an adequate heart rate. Asystole after the cessation of pacing has been observed even in patients who previously had been stable with only rare or minimal symptoms before pacemaker placement.

The achievement of therapeutic serum levels with the use of lidocaine for local anesthesia has been reported.[1] Since subcutaneous lidocaine is commonly used during pacemaker implantation, we investigated the possibility that this drug might be responsible for the emergence of pacer dependency.

In this study 7 of 9 patients achieved therapeutic drug levels after subcutaneous lidocaine administration during permanent pacemaker implantation. The level attained appeared to be related to the total dose administered, although the resulting maximal serum lidocaine levels were not as predictable as the results reported by Nattel et al.[1] In their study the peak lidocaine concentration could be predicted by multiplying the initial dose (in milligrams/kilogram) by 0.3. However, they noted the peak concentration to occur at an average of 62 minutes after subcutaneous injection, which was beyond the duration of our observations.

In unanesthesized dogs with complete heart block, Hayes et al[3] showed that lidocaine prolonged asystole after abrupt cessation of ventricular driving. Ryden and Korsgren[4] studied the effects of sudden cessation of pacing in 6 patients before and after 2 intravenous boluses of 1 to 2 mg/kg of lidocaine. In some patients this was followed by an intravenous drip of the medication, and blood levels were not measured. All of their patients reestablished an autonomous ventricular rhythm before lidocaine administration without any period of asystole of clinical importance. After lidocaine, 3 patients developed prolonged asystole which necessitated pacing after 8 seconds. Two of these patients had third-degree block and the remaining patient had second-degree atrioventricular block. Roos and Dunning[5] examined the acute effects of the rapid intravenous injection of 100 mg lidocaine in patients with a variety of conduction defects. Despite a mean arterial plasma level of 26.6 $\mu$g/ml, no effect was seen on the spontaneous firing rate of the escape focus in any of the 5 patients with complete heart block. This group included those with block distal and proximal to the His bundle.

Aravindakshan et al[6] administered lidocaine intravenously to 18 patients with complete atrioventricular block. They employed a bolus dose of 1.5 mg/kg followed by a 2 to 4 mg/min infusion. In 13 cases, there was little or no slowing of the escape rate. In the remaining 5 patients there was an abrupt slowing of the rates with resulting R-R intervals that grossly approximated multiples of the basic escape intervals, thus suggesting the occurrence of 2:1 or 3:1 exit block rather than slowing of the escape focus. They claimed that the development of exit block depended more on a critical degree of His-Purkinje conduction abnormality than on the plasma drug level achieved. Furthermore, they concluded that the basic QRS complex duration and escape rate were of no value in identifying those patients prone to abrupt rate slowing.

In the present study, lidocaine produced a lengthening of the mean and maximal escape intervals after the abrupt cessation of pacing in every patient. Of the 9 patients, the longest escape interval during the 3 to 6 determinations in the control period was 2.56 seconds. After lidocaine administration, 5 patients had escape intervals of >4 seconds at the time of their maximal drug concentration and 1 patient needed to have his pacemaker turned back on due to presyncopal symptoms or >6 seconds of asystole. The prolongation of escape interval was present by 10 minutes after injection and persisted for more than 45 minutes. The degree of prolongation of the escape interval was directly related to the maximal drug level achieved (Fig. 3), and the duration of asystole after lidocaine administration could not be predicted by the escape interval in the control state nor by the QRS duration. Three of our patients had QRS durations of $\leq$0.08 second; therapeutic levels of lidocaine were achieved in 2 of these patients. Both of these patients developed asystole lasting >4 seconds and 1 required the resumption of ventricular pacing. The lengths of the escape intervals before and after lidocaine injection do not suggest the existence of exit block.

Thus, prolonged asystole after abrupt cessation of pacing in patients with complete heart block is more likely to occur after lidocaine administration. Concentrations adequate to affect escape intervals are reached in a majority of patients undergoing routine permanent pacemaker implantation using local lidocaine anesthesia. To avoid problems related to asystole and allow proper threshold measurements, it is advisable to minimize the systemic concentration of this medication. This can be achieved by limiting the total dose used to the minimal amount necessary to achieve adequate local anesthesia. It is possible that the use of a vasoconstrictor mixed with the anesthesia may limit the distribution of the drug and thereby blunt or delay the peak systemic lidocaine concentration. However, the safety of such agents would need to be established in this patient population. Further study would also be necessary to assess the effects of alternate local anesthetic agents. Finally, strong consideration should be given to the routine use of temporary pacing in patients with complete heart block during permanent pacemaker implantation, even in the absence of prior asystole.

# Relation Between Late Potentials on the Body Surface and Directly Recorded Fragmented Electrograms in Patients With Ventricular Tachycardia

MICHAEL B. SIMSON, MD, WILLIAM J. UNTEREKER, MD, SCOTT R. SPIELMAN, MD, LEONARD N. HOROWITZ, MD, NORMAN H. MARCUS, MD, RITA A. FALCONE, BS, ALDEN H. HARKEN, MD, and MARK E. JOSEPHSON, MD

**The relation between low-amplitude, late potentials on the body surface and directly recorded electrograms in 8 patients with and 11 patients without ventricular tachycardia (VT) was studied. Bipolar X,Y,Z leads were signal-averaged and filtered with a digital technique. All patients had catheter endocardial left ventricular maps. The VT group had medically intractable VT and an endocardial excision was performed for control of VT. Before bypass, epicardial maps were obtained in the operating room. All studies were performed during normal sinus rhythm.**

**Four patients without VT, each with a previous myocardial infarction, had fragmented endocardial electrograms recorded at 2.0 ± 1.2 sites. The latest electrogram for each patient ended 87 ± 8 ms after QRS onset, within the high-amplitude portion of the filtered QRS complex. All patients with VT had fragmented electrograms recorded at 6.1 ± 3.1 sites/patient. Eighty-eight percent of the fragmented electrograms were endocardial. The latest fragmented electrogram for each patient ended 161 ± 43 ms after QRS onset, significantly later than the fragmented electrograms from the patients without VT ($p = 0.002$).**

**Six VT patients had low-amplitude, late potentials at the end of the filtered QRS complex. In these patients, the last 40 ms of the filtered QRS complex contained a higher proportion of fragmented electrograms compared with earlier segments of the QRS complex (68% versus 27%, $p < 0.001$). Two patients with VT did not have late potentials. One patient with left bundle branch block had delayed left ventricular epicardial activation which masked the fragmented electrograms. The other had fragmented electrograms of brief duration which ended 80 ± 12 ms after QRS onset, during the time of normal ventricular activation.**

**It is concluded that the late potential corresponds to delayed, fragmented electrographic activity. Failure to record a late potential may arise from delayed ventricular activation at other sites from bundle branch block or fragmented electrograms of a brief duration.**

Delayed and fragmented electrograms have been recorded directly from the myocardium in patients and animals with ventricular arrhythmias.[1–9] The association of delayed electrical activity with VT suggests a reentrant mechanism. This concept is supported by the demonstration that the initiation and maintenance of the arrhythmias depends on the delayed electrogram spanning diastole before the onset of the first and between subsequent complexes of the tachycardia.[2,4–6,8]

In recent years, investigators working with signal averaging techniques have detected low-amplitude potentials on the body surface in patients and animals with ventricular arrhythmias.[10–19] These potentials occur at the end of or just after the QRS complex; in animals with experimental infarcts, the late potentials correlated in time to directly recorded fragmented electrograms.[10–17]

In previous work, we demonstrated that 90% of patients with VT after myocardial infarction (MI) had a distinctive low-amplitude, late potential that was continuous with the earlier portions of the QRS complex.[16,18,19] A similar potential was found in only 6% of patients without serious ventricular arrhythmias after MI. The purpose of this work was to identify the origin of the low-level late potential by correlation with directly recorded epicardial and endocardial ventricular electrographic maps.

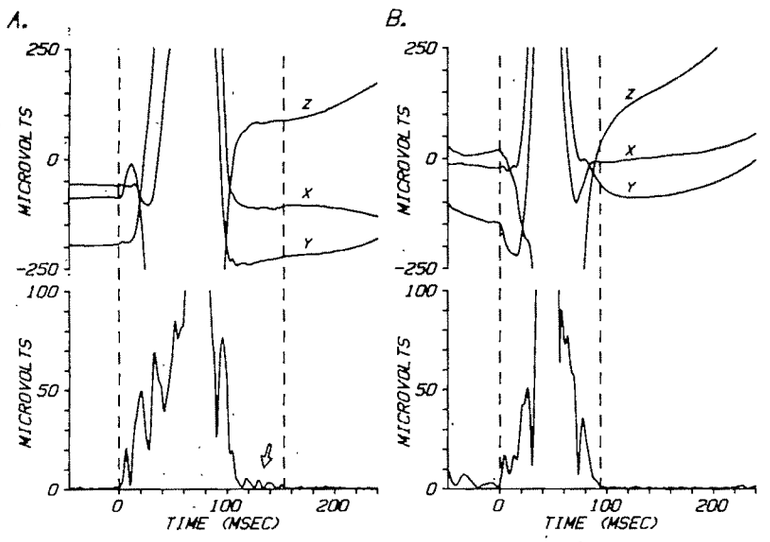

**FIGURE 1.** Patients 4 and 15. Signal processing in patients with (**A**) and without (**B**) VT. Signal-averaged X, Y, Z leads are shown at high gain on the top. The filtered QRS complex is on the bottom. The **dashed lines** are the end points of the filtered QRS complex as determined by the computer. The **arrow** points to a low-amplitude (4 $\mu$V), late potential at the end of the filtered QRS complex from the patient with VT. Both patients had anterior myocardial infarctions.

## Methods

**Patient population:** Nineteen patients were studied. Eight patients had VT; all had a prior MI. They were referred to our institution for recurrent, symptomatic VT which was inducible in the clinical electrophysiology laboratory with 1 to 3 ventricular premature depolarizations.[20] In each patient, the VT could not be controlled with antiarrhythmic agents,[21] and an endocardial excision with or without an aneurysmectomy was performed for control of the arrhythmia.[22,23] Endocardial and epicardial mapping and a signal-averaged electrocardiograph was performed in each patient.

Eleven other patients were studied with a signal-averaged electrocardiogram and endocardial mapping. These patients were referred to the catheterization laboratory for evaluation of chest pain, and they volunteered for a research study of endocardial activation. The patients had no history of VT or complex ventricular arrhythmias. Holter monitoring was performed for 24 hours in 8 patients and showed 0 to 10 unifocal ventricular premature beats/hour and the absence of multiform ventricular premature beats, couplets, or VT.

Table I lists the clinical data on all patients. Each patient gave informed consent. The research protocols were approved by the University of Pennsylvania Committee on Studies Involving Human Beings.

**Signal-averaged electrocardiograms:** A signal-averaged electrocardiogram was recorded from bipolar X,Y,Z leads with previously described techniques.[16] Ectopic and grossly noisy beats were rejected by a template algorithm. A mean of 142 ± 12 beats was averaged. Each lead was filtered with a bidirectional, high-pass digital filter which was designed to eliminate filter ringing.[16] The bandpass was 25 to 250 Hz and the rate of highpass attenuation was 24 dB/octave. The filtered X,Y,Z leads were combined into a vector magnitude—$\sqrt{(X^2 + Y^2 + Z^2}$—a measure which sums the high-frequency information from all 3 leads and which is termed the "filtered QRS complex" in this study. The end points of the filtered QRS complex were determined by a computer algorithm.[16]

Figure 1 shows results of signal processing in patients with and without VT. In previous studies,[16,18,19] a prolonged filtered QRS duration and a low voltage in the last 40 ms of the filtered QRS complex were found to identify patients with VT; those variables were used in the present study to quantify the filtered QRS complex. In this study a "late potential" is defined as a low-amplitude signal (<25 $\mu$V) in the last 40 ms of the filtered QRS complex (Fig. 1, arrow). It is called late because it typically occurs after end of the QRS complex in the standard electrocardiogram.

Left ventricular endocardial electrograms were recorded in the catheterization laboratory by bipolar electrodes with an interelectrode distance of 1 cm. The amplifier bandpass was 30 to 500 Hz. An attempt was made to record from 12 preselected endocardial sites with methods previously described[24]; occasionally, a preselected site could not be reached. Additional recordings were made, if possible, from the edges of aneurysms or infarcts, Table I lists the number of endocardial sites for each patient. There was no difference in the

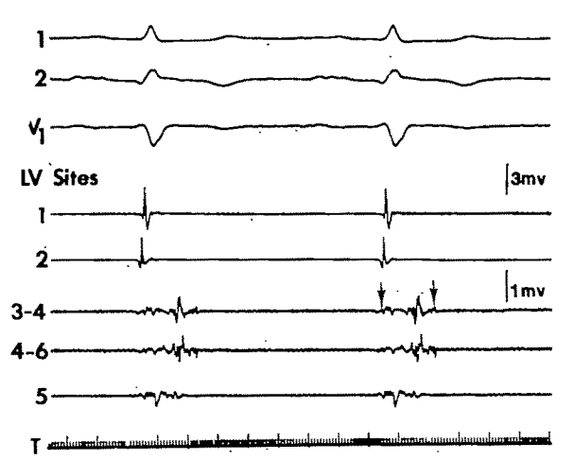

**FIGURE 2.** Examples of electrogram classification. **Top,** 3 surface electrocardiographic leads; **bottom,** 5 endocardial electrograms. Electrograms from sites 1 and 2 (apex) were normal. Electrograms from the other sites were fragmented. The **arrows** indicate the end points of a fragmented electrogram. Sites 3 through 6 are in the inferobasal portion of the heart. The voltage calibration is 3 mV for the normal electrograms and 1 mV for the fragmented electrograms. LV = left ventricular.

Patients 5 and 6 had, in addition, fragmented electrograms at 4 and 2 epicardial sites, respectively. AMI = anterior myocardial infarction; ANT = anterior; CAD = coronary artery disease; ECG = electrocardiogram; IMI = inferior myocardial infarction; INF = inferior; LAT = lateral; LBBB = left bundle branch block; NL = normal.

number of endocardial sites studied for the patients with and without VT ($p = 0.36$). Sites were identified with multiplane fluoroscopy. These methods have been validated by comparison with intraoperative data.[25]

In the operating room, epicardial electrograms were recorded from the patients with VT under halothane anesthesia before cardiopulmonary bypass as previously described.[22,23] A roving, bipolar electrode with a 1.5 mm interelectrode distance was used. The amplifier bandpass was 30 to 500 Hz. Recordings were made from 54 predetermined sites (29 left ventricular sites) in each patient. Intraoperative right bundle branch block temporarily developed in 3 patients, and the right ventricular sites were not analyzed further in those patients.

Each patient was in sinus rhythm during all studies. Antiarrhythmic agents were stopped at least 5 half-lives before the studies. The signal-averaging, catheter, and intraoperative studies were performed within 3 to 5 days of one another.

All electrograms were classified as normal or fragmented (Fig. 2). An electrogram was considered normal if the duration was <60 ms and the peak to peak amplitude was >1 mV. (Sixty ms was used as a threshold since it was >2 standard deviations larger than the mean duration of 100 electrograms recorded over the normal left ventricle in pilot studies.) A fragmented electrogram had multiple components, a duration >60 ms, and a peak-to-peak amplitude typically <1 mV. The electrographic duration was measured from the beginning to the end of the rapidly moving components of the electrogram. The fragmented electrograms had a constant duration in this study; no examples of a Wenckebach conduction pattern were found.[5,6] The time of peak amplitude for the normal electrograms was considered to be the time of occurrence. The QRS onset was used as the reference time for all studies. The calibration of the oscillographic recorder was 1 mV/cm and 40

The incidence and timing of the fragmented electrograms in patients with and without VT. In the "No VT" group the data are tabulated only from patients with fragmented electrograms. SD = standard deviation.

ms/cm. Electrograms were measured by observers who did not know the signal-averaged results. Statistical analysis was performed using 2 × 2 chi-square, RxC contingency table, and the *t* test (1-tail), as appropriate. Except as noted, all voltages were measured by the root mean square method. Results are presented as the mean ± standard deviation.

## Results

**Patients without VT:** Fragmented endocardial electrograms were found in 4 of the 6 patients with prior MI and were not found in the 5 patients without previous MI. The fragmented electrograms were located within areas showing wall motion abnormalities from the previous infarct. Table II summarizes the incidence and timing of the fragmented electrograms.

The mean time of activation for the normal endocardial electrograms was 23 ± 15 ms (range 0 to 54); the mean and median time of activation agreed within 0.7 ms (p = 0.18).

The filtered QRS complex from patients without VT was a symmetrical burst of high-frequency signal. No late potentials were found in these patients. The filtered QRS duration was 96 ± 8 ms, and the voltage in the last 40 ms was 51.5 ± 26.5 μV. Among patients without VT, there was no significant difference between patients with and without fragmented electrograms in filtered QRS duration (98 ± 6 versus 95 ± 9 ms, p = 0.23) or voltage in the last 40 ms (38.9 ± 12.5 versus 58.6 ± 80.4 μV, p = 0.13).

Figure 3 shows the time relation between the endocardial electrograms and the filtered QRS complex in patients with (Fig. 3A) and without (Fig. 3B) fragmented electrograms. Since the fragmented electrograms ended 84 ± 6 ms after QRS onset (Table II), they were contained within the high-amplitude portions of the filtered QRS complex.

**Patients with VT:** Fragmented electrograms were found in each patient with VT. Eighty-eight percent of the sites with fragmented electrograms were endocardial

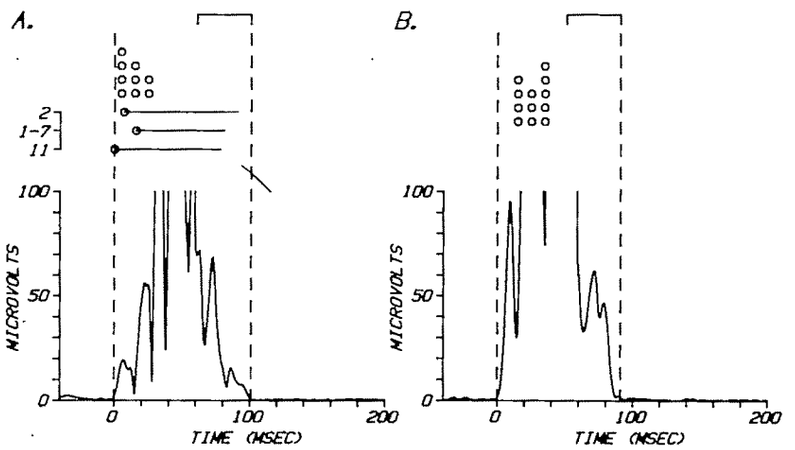

**FIGURE 3.** Patients 13 and 18. Examples of the time relations between the endocardial electrograms and the filtered QRS complex in patients with (**A**) and without (**B**) fragmented electrograms. Neither patient had VT. **Bottom,** filtered QRS complex; the **circles on top** indicate the timing of the endocardial electrograms. Normal electrograms are shown with an **isolated symbol.** Fragmented electrograms are depicted with a **line,** which indicates the duration of the electrogram. The **brackets** indicate the last 40 ms of the filtered QRS complex. The **numbers** indicate electrographic sites. The patient shown in **A** had 3 fragmented endocardial electrograms which ended 78, 81, and 91 ms after QRS onset.

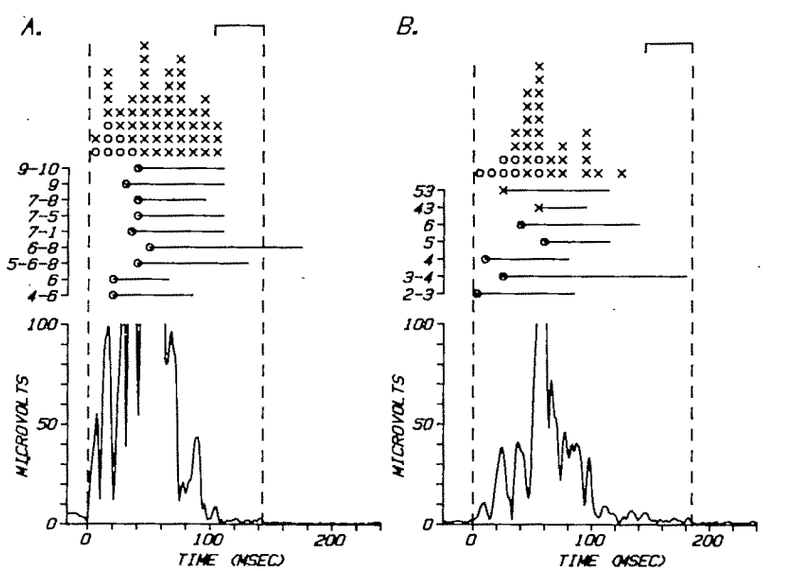

**FIGURE 4.** Patients 1 and 6. Examples of the time relation between the electrograms and the filtered QRS complex in 2 patients with VT. **Bottom,** filtered QRS complex. The **symbols on the top** indicate the timing of the electrograms. An **X** represents an epicardial electrogram and a **circle** represents an endocardial electrogram. Fragmented electrograms are indicated with a **line** which shows the timing and duration of the electrogram. The **brackets** indicate the last 40 ms of the filtered QRS complex. See text for details.

despite the fact that more epicardial than endocardial sites were sampled. Fragmented epicardial electrograms were found only in 2 patients at 2 and 4 sites, respectively. All fragmented electrograms were found within areas of previous infarct. They were found more frequently, began later, and ended later in patients with VT than in those with fragmented electrograms but without VT (Table II). The latest fragmented electrogram for each patient ended 161 ± 43 ms after QRS onset for the VT group, but only 87 ± 8 ms for the patients without VT ($p = 0.002$).

The time of activation for the normal endocardial electrogram was later in the VT group than in the group without VT (38 ± 30 versus 23 ± 15 ms, $p < 0.001$). If patients with intraventricular conduction delay or left bundle branch block were excluded, however, the time of endocardial activation was similar (26 ± 15 ms, range 0 to 48, $p = 0.15$). The latest normal electrograms (epicardial and endocardial) occurred 108 ± 25 ms after QRS onset in the VT patients. When patients with ventricular conduction delay were excluded, the latest normal electrogram occurred at 92 ± 9 ms.

The normal electrograms had a symmetrical time distribution; the median and mean time of activation agreed within 1.4 ± 5.5 ms ($p = 0.26$). The normal electrograms tended to cluster; within 40 ms of the latest normal electrogram, there were 18.8 ± 12.1 other sites showing normal configuration (37.2 ± 20.9% of all normal electrograms).

The filtered QRS complex differed in the patient with and without VT. The filtered QRS duration was longer (148 ± 29 ms versus 96 ± 8 ms, $p < 0.001$) and the voltage in the last 40 ms was lower (16.0 ± 20.4 versus 51.5 ± 26.5 μV, $p = 0.007$).

**VT patients with late potentials:** Six patients with VT had a distinctive, low-amplitude tail at the end of the filtered QRS complex; these patients met the criterion for VT we had developed earlier, that is, <25 μV of signal in the last 40 ms of the filtered QRS complex.[16] For these patients, the voltage during that time was 8.7 ± 7.2 μV and the filtered QRS duration was 154 ± 28 ms.

Figure 4 shows the time relation between the electrograms and the filtered QRS complex in 2 patients. In Figure 4A, the patient had fragmented activity at 9 endocardial sites. During the last 40 ms, there is a low amplitude of signal in the filtered QRS complex. During that time, 6 fragmented electrograms were present and only 3 normal electrograms occurred. For most of the 40 ms, the low-level body surface signal corresponded to 2 fragmented electrograms. Earlier in the QRS, when a large amplitude of high-frequency signal was present on the body surface, 59 normal electrograms were recorded. Some fragmented electrograms (for example, locations 4-6 and 6) had a brief duration and ended before all normal electrograms had occurred.

Figure 4B shows another example from a patient with a low-amplitude (3 μV) signal at the end of the filtered QRS complex. There were 7 fragmented electrograms (2 epicardial, 5 endocardial). During the last 40 ms of the filtered QRS complex, only 1 site was active and it showed fragmented activity. In contrast, 35 normal electrograms were found at an earlier time. Intraoperative right bundle branch block occurred in this patient and only the data from the left ventricle was analyzed.

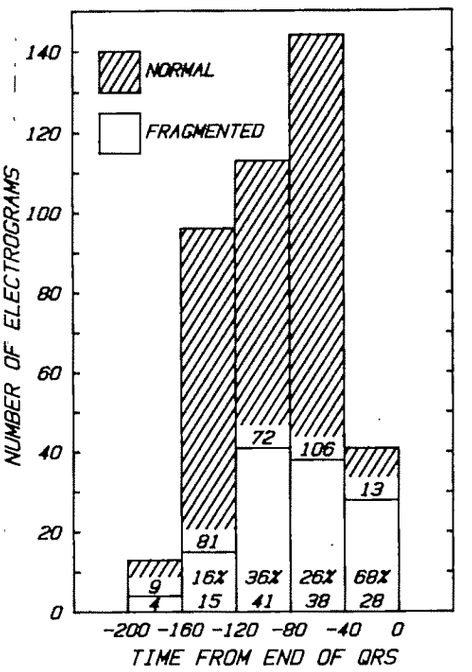

**FIGURE 5.** The number of normal and fragmented electrograms detected in various time segments of the filtered QRS complex in 6 VT patients with late potentials. The filtered QRS complex was divided into 40 ms segments, beginning at the end of the filtered QRS complex. The number of electrograms which were active in each time segment are indicated. The percentage of the total number of electrograms in each time segment which were fragmented is also shown.

In the 6 patients with late potentials, the latest fragmented electrograms lasted a mean of 54 ± 31 ms beyond the latest normal electrogram in each patient. There were 3.3 ± 2.9 fragmented electrograms/patient that persisted >20 ms beyond the latest normal electrogram. There was a high proportion of fragmented electrograms during the last 40 ms of the filtered QRS complex (Fig. 5). Relatively few (13) normal electrograms were active during that time; only 4.6% of the total number of normal electrograms occurred then. In the last 40 ms, 41 electrograms were active and 28 (68%) were fragmented. Earlier in the QRS, there were 309 electrograms detected and the proportion of fragmented electrograms in any 40 ms segment was lower (mean 27%, range 16 to 36, $p < 0.001$).

**VT patients without late potentials:** Two patients with VT did not have the low-amplitude signal at the end of the filtered QRS complex. One had left bundle branch block (Fig. 6A). The electrograms with normal configuration were delayed and obscured the signal from the fragmented electrograms. During the last 40 ms there were 4 fragmented and 10 normal electrograms. The body surface signal was 46 μV during that time. In addition, this patient did not have a peak of

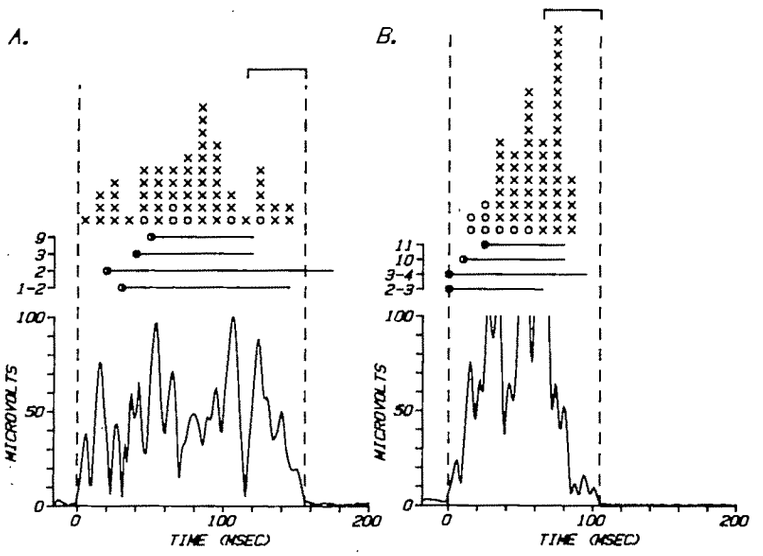

**FIGURE 6.** Patients 8 and 4. Time relation between the filtered QRS complex and electrograms in the 2 patients with VT who did not have late potentials. Symbols as in Figure 4. See text for details.

high-frequency signal in the first 100 ms of the filtered QRS complex; in contrast to all other patients, the high-frequency signal had a more uniform level over 156 ms.

Figure 6B shows the records from the other patient with VT who did not have a low-amplitude, late potential. The voltage during the last 40 ms was 59 $\mu$V. During that time there were 3 fragmented and 25 normal electrograms. The fragmented electrograms were brief and ended 80 ± 12 ms after QRS onset. The other patients with VT had longer fragmented electrograms that ended 122 ± 36 ms after QRS onset ($p = 0.01$).

The 2 VT patients without the late potentials had a low proportion of fragmented electrograms during the last 40 ms of the filtered QRS complex. In these patients, only 17% of the electrograms in the last 40 ms were fragmented (7 fragmented, 35 normal electrograms); in contrast, 68% of the electrograms in the last 40 ms were fragmented in the patients with the low-amplitude signal ($p < 0.001$). In the 2 patients without late potentials there was no significant difference in the proportion of fragmented electrograms active in each 40 ms segment of the QRS; a mean of 18% (range 13 to 24) of the electrograms in each segment were fragmented ($p = 0.59$).

In the results discussed so far, the normal electrograms were analyzed according to the time of their peak amplitude. Data were reanalyzed taking into consideration the total duration of the normal electrograms, which was 43 ± 6 ms. The VT patients with the late potentials had a high proportion of fragmented electrograms in the last 40 ms compared with the other segments of the QRS complex ($p < 0.001$). Similar results were found when only left ventricular epicardial sites were analyzed ($p < 0.001$).

For the patients with VT, the filtered QRS voltage at a particular time correlated with the number of sites with active electrograms at that time. The mean linear correlation coefficient was 0.80 (range 0.51 to 0.96), and the mean slope was 5.6 $\mu$V (range 3.2 to 9.4) per electrographic site. The body surface voltage associated with fragmented electrograms was estimated from 5 patients with VT who had a 20 to 60 ms segment of the filtered QRS complex during which normal electrograms were not present. The mean voltage was 2.0 ± 0.4 $\mu$V/site showing fragmented activity.

## Discussion

This study used 2 advanced signal processing techniques to record low-level potentials on the body surface: signal-averaging and a bidirectional high-pass filter. Signal-averaging reduces random noise, which arises primarily from muscle, and allows the detection of microvolt level signals which would otherwise be obscured by noise. The high-pass filter sharply attenuates low-frequency activity, but allows high-frequency potentials to pass without reduction. The filtering allows one to detect electrical activity arising from changes in conduction velocity or direction of activation,[26] and simultaneously suppresses the low-frequency activity that originates from the plateau phase of the action potentials. The filter we used had excellent attenuation of low-frequency events; in the S-T segment of all patients, there was no signal other than random noise, a mean of 0.6 $\mu$V. The filter operated in a bidirectional mode to eliminate filter ringing, an artifact which would mask a low-amplitude signal that occurred immediately after a larger signal, such as the QRS complex.[16]

In previous work, we demonstrated that 90% of patients with VT after MI had a distinctive low-amplitude, late potential which was continuous with the earlier portions of the QRS complex.[16,18,19] A similar potential was found in only 6% of patients without serious ventricular arrhythmias after MI. A low level of signal in the last 40 ms of the filtered QRS complex (<25 $\mu$V) iden-

tified patients with VT with 90% sensitivity and 94% specificity. Several groups of investigators have identified a similar low-amplitude, late potential in patients with VT.[11–15]

The purpose of this work was to identify the origin of the low-level, late potential by correlation with directly recorded epicardial and endocardial ventricular electrographic maps. In 6 patients with VT the late potential occurred at a time when a high proportion of active electrode sites showed fragmented activity. During the time of low-amplitude signal, 68% of the active electrograms were fragmented. In contrast, only 27% of active electrograms were fragmented earlier in the QRS complex (Fig. 5). The 2 patients with VT without late potentials did not have a high proportion of fragmented electrograms late in the QRS complex. No low-level, late potentials were found in 4 patients without VT who had fragmented electrograms after MI; the longest fragmented electrogram in those patients ended a mean of 87 ms after QRS onset, presumably during normal ventricular activation.

The condition necessary to detect slow ventricular activation on the body surface is that the disorganized and delayed activation must outlast normal ventricular activation. When fragmented electrograms were brief in duration, no distinctive signal was identified. Conversely, in the 6 VT patients with late potentials, the longest fragmented electrograms outlasted the latest normal electrogram by 54 ms.

This study offers insight on why a low-amplitude signal at the end of the filtered QRS complex identified patients with VT in our previous studies. First, the signal from delayed ventricular activity is low level. Only a few sites have fragmented electrographic activity late in the QRS complex; in the 6 VT patients with the late potentials a mean of only 3.3 sites lasted 20 ms beyond the latest normal electrogram. Each site with fragmented activity, moreover, was associated with a low-level signal on the body surface, estimated at 2 $\mu$V/site. Second, normal ventricular activation generates a high-level, symmetrical burst of high-frequency energy. This was apparent on examination of the filtered QRS complex from patients without VT (Fig. 1 and 3). The normal electrograms had a symmetrical time distribution; the mean and median times of activation agreed within 2 ms. In the patients with VT, the normal electrograms tended to cluster together in time as expected from the syncytial nature of myocardium; within the 40 ms preceding the latest normal electrogram, a mean of 19 sites with active normal electrograms was detected. As a consequence, normal ventricular activation causes a relatively high amplitude of high-frequency voltage on the body surface which ends abruptly, in contrast to the low-level signal that fragmented and delayed ventricular activation creates. The distinguishing criterion for detecting delayed and fragmented ventricular activation is a low-amplitude potential which persists at the end of the QRS complex. This study suggests that the low-amplitude signal represents disorganized and delayed activation within 1 or more protected sites and is in agreement with the findings of Fontaine,[11] Breithardt,[14] Rozanski[15] and their co-workers, who have reported examples of fragmented epicardial and endocardial electrograms which correlated in time with late potentials.

The 2 patients with VT who did not have the low-amplitude, late potential illustrate limitations of the signal-averaging technique. Patients with bundle branch block may have sufficient delay in epicardial activation that masks the fragmented electrical activity elsewhere in the heart. Also, some patients with VT may not have fragmented electrographic activity of sufficient duration to allow detection from the body surface during sinus rhythm (Fig. 6). In our previous studies,[16,18,19] we found the incidence of failure to detect delayed potentials among VT patients without bundle branch block to be 10%, possibly because of insufficient delay of ventricular activation. Rapid pacing or insertion of a premature beat may improve the sensitivity of the signal-averaging technique by prolonging the duration of delayed ventricular activity.[5,6,8]

Several technical difficulties in this study should be noted and require further investigation. First, the patients without VT did not have ventricular aneurysms, yet all but 1 of the patients with VT had an aneurysm. A more appropriate control group, and one more difficult to obtain, would be patients with ventricular aneurysms yet without ventricular arrhythmias. However, in previous studies late potentials were found in patients with VT but without ventricular aneurysms, and the voltage late in the filtered QRS complex was nearly identical in patients with VT despite the presence or absence of an aneurysm.[16] These findings suggest that the late potential is related to the VT and not to the ventricular aneurysm.

Second, standards should be developed to define the end points of normal and fragmented electrograms. At sufficiently high gain and with a low noise level, an electrode will record distant activity. With fragmented electrograms, the difficult of defining the end points increases. From our previous experience with ventricular mapping, we used the rapidly moving components of the electrograms to establish the end points; we recognize that this definition is somewhat arbitrary. Third, the epicardial electrodes we used had a smaller interelectrode distance (1.5 mm) than the catheter endocardial electrode (1 cm). Data from animal studies suggest that increasing the interelectrode distance does not significantly prolong the endocardial electrogram[27]; similar studies are needed in humans, especially in regions of myocardium with delayed and fragmented electrical activity.

Finally, since the signal-averaging and mapping studies were not simultaneous, it is not clear whether failure to detect some fragmented activation (as site 6-8, Fig. 4A) on the body surface represents a lack of sufficient sensitivity by the signal-averaging technique or a change in duration of the fragmented electrogram over time.

# Clinical Spectrum of Ventricular Tachycardia With Left Bundle Branch Morphology

MICHAEL J. REITER, MD, PhD, WARREN M. SMITH, MD, and JOHN J. GALLAGHER, MD

**Twenty-nine patients with apparent ventricular tachycardia (VT) of left bundle branch block (LBBB) morphology were evaluated. Tachycardia was associated with an organic basis in 24 of 29 patients: 7 had Mahaim fibers of the nodoventricular type, 7 had arrhythmogenic right ventricular dysplasia, 5 had coronary heart disease, 3 had biventricular cardiomyopathy, and 2 had associated congenital heart disease.**

**In many patients the underlying cardiac disease was not readily apparent. In the patients with a Mahaim fiber, the electrocardiogram taken during sinus rhythm was frequently normal. A reentry tachycardia with anterograde conduction over the nodoventricular fiber could mimic VT as diagnosed by the usual criteria; nodoventricular fibers were, therefore, often unsuspected before electrophysiologic evaluation. In patients with arrhythmogenic right ventricular dysplasia, cineangiography demonstrated abnormalities of the right ventricle, but only minor or no abnormalities of the left ventricle. Clinical and electrocardiographic features were not distinctive. Of the 29 patients, 22 had serious symptoms accompanying the tachyarrhythmia or had required cardioversion. Patients were followed up for an average of 20 months: 4 patients died. Thus, VT exhibiting an LBBB morphology is not uncommon and is frequently associated with organic heart disease, serious symptoms, and significant mortality. Right ventricular angiography and electrophysiologic study may clarify the diagnosis in these patients.**

Recurrent VT may be a manifestation of a variety of organic heart diseases with differing prognostic and therapeutic significance. It is often difficult to distinguish between the various causes based on clinical features alone. The QRS morphology of the VT has sometimes been assumed to convey useful diagnostic information by indicating the ventricle of origin[1–6]—tachycardia having an LBBB morphology originating from the right ventricle and tachycardia having a right bundle branch block (RBBB) morphology originating from the left ventricle. It was recently shown, however, that the assignment of the origin of the tachycardia on the basis of the bundle branch block morphology of the tachycardia may be misleading.[7,8] Nevertheless, it is frequently suggested that premature ventricular beats or VT with an LBBB morphology imply a benign prognosis and are often unassociated with organic heart disease.[2,6,9,10] These observations have not been confirmed by other investigators,[11,12] and the significance of VT with an LBBB morphology remains unknown. This report assesses the implications of a tachycardia exhibiting an LBBB morphology among patients referred to this institution for evaluation of recurrent VT.

## Methods

Patients referred to Duke University Medical Center with presumed recurrent VT as defined by electrocardiographic or His bundle electrographic criteria were eligible for the study. Patients with intact atrioventricular accessory pathways were excluded. VT was diagnosed when a wide QRS tachycardia with either atrioventricular dissociation (on the surface electrocardiogram or documented by eosphageal recording), atrial capture beats, or fusion beats were identified. In equivocal cases, VT was diagnosed if the QRS complex during the tachycardia was not preceded by a His bundle deflection or was preceded by a His deflection at an H-V interval shorter than that seen during sinus rhythm.[13] At least 2 documented episodes of sustained VT (≥1 minute) were required for inclusion in this study. In most cases, the number of episodes far exceeded this minimum. Patients with myocardial infarction within the preceding 6 weeks, suspected

ARVD = arrhythmogenic right ventricular dysplasia; ASD = atrial septal defect; CABG = coronary artery bypass graft; CAD = coronary artery disease; CP = chest pain; CPA = cardiopulmonary arrest; CREST = calcinosis, Raynaud's phenomenon, esophageal hypomotility, sclerodactyly, and telangiectasia; EEV = encircling endocardial ventriculotomy; LV = left ventricle; MVP = mitral valve prolapse; NVF = nodoventricular fiber; PA = procainamide; RV = right ventricle; RVOT = right ventricular outflow tract; S/P = status post; VT = ventricular fibrillation.

drug toxicity, or an acute precipitating cause of VT were excluded. No patient exhibited a Q-T prolongation syndrome. Fifty patients who fulfilled these criteria and who underwent electrophysiologic study comprise the study population.

LBBB morphology was diagnosed when the QRS complex exceeded 120 ms and was predominantly negative in lead $V_1$ with a terminal S wave. RBBB morphology was diagnosed when there was a predominantly positive QRS complex in lead $V_1$ with a terminal R wave. Serious arrhythmias were defined by the occurrence of seizure, syncope, shock, or cardiac arrest in association with the tachycardia.

All patients were placed on continuous telemetry upon admission to the hospital. When appropriate, all cardioactive medications were discontinued before study. All patients had a history and physical examination, routine blood work, electrocardiogram, and chest x-ray before electrophysiologic study. Each patient underwent additional evaluation to determine the nature and extent of organic heart disease. The specific studies were dictated by the clinical circumstances but frequently included right or left heart catheterization, or both, and ventriculography, coronary angiography, 2-dimensional (2-D) echocardiography, and radionuclide angiography. M-mode and 2-D echocardiography were performed using standard techniques.[14,15] Single-pass and multigated radionuclide angiography were performed after the intravenous injection of 30 mCi of technetium-99m using standard techniques.[16]

All but 1 patient underwent electrophysiologic study by the catheter technique (43 patients) or intraoperative study (13 patients), or both, using techniques fully described elsewhere.[17,18] During the study in the electrophysiology laboratory, the right atrial catheter was advanced into the right ventricle for purposes of mapping during tachycardia or for programmed intracardiac stimulation from multiple sites (apex, high and low outflow tract, septum, and inflow tract) within the right ventricle. The protocol for inducing VT included the introduction of (1) progressively more premature single, then (2) double extrastimuli during ventricular pacing at 1 or more pacing rates, and (3) bursts of rapid pacing from the apex of the right ventricle, right ventricular outflow tract, or left ventricle. Termination of the tachycardia was attempted using single or double premature extrastimuli and rapid ventricular pacing. Left ventricular pacing was accomplished by way of either the distal electrode pair of the coronary sinus catheter or retrograde catheterization of the left ventricle from the right femoral artery. No serious complications were encountered.

## Results

Of our 50 patients (Fig. 1), 58% had VT exhibiting an LBBB morphology. No organic basis for the tachycardia was found in 5 of the 29 patients with LBBB morphology (a proportion similar to that found in patients with RBBB morphology, 3 of 18 patients). The other 24 patients with tachycardia having LBBB morphology had 1 of the following causes: Mahaim fiber of the nodoventricular type (7 patients), arrhythmogenic RV dysplasia (7 patients), coronary artery disease (5 patients), biventricular cardiomyopathy (3 patients), or congenital heart disease (2 patients) (Table I).

**Patients with nodoventricular Mahaim fibers:** Patients with a nodoventricular fiber tended to be younger than other patients with tachycardia exhibiting an LBBB morphology with a mean age of 20 years (range 4 to 34). Palpitations were the most common presenting symptom and serious symptoms were infrequent. One patient had had syncope during tachycardia and 5 patients had a history of cardioversion. Associated cardiac disease (Ebstein's anomaly, atrial septal defect, atrioventricular accessory pathway) was not uncommon.

During sinus rhythm, all patients with a nodoventricular fiber had a normal P-R interval. The configuration of the QRS complexes in sinus rhythm either showed varying degrees of LBBB morphology (5 patients) (Fig. 2) or was consistently normal (2 patients). Only a single morphology was observed during spontaneous tachycardia.

The presence of a nodoventricular fiber in these patients and its anterograde involvement in a reentry tachycardia was demonstrated by previously described

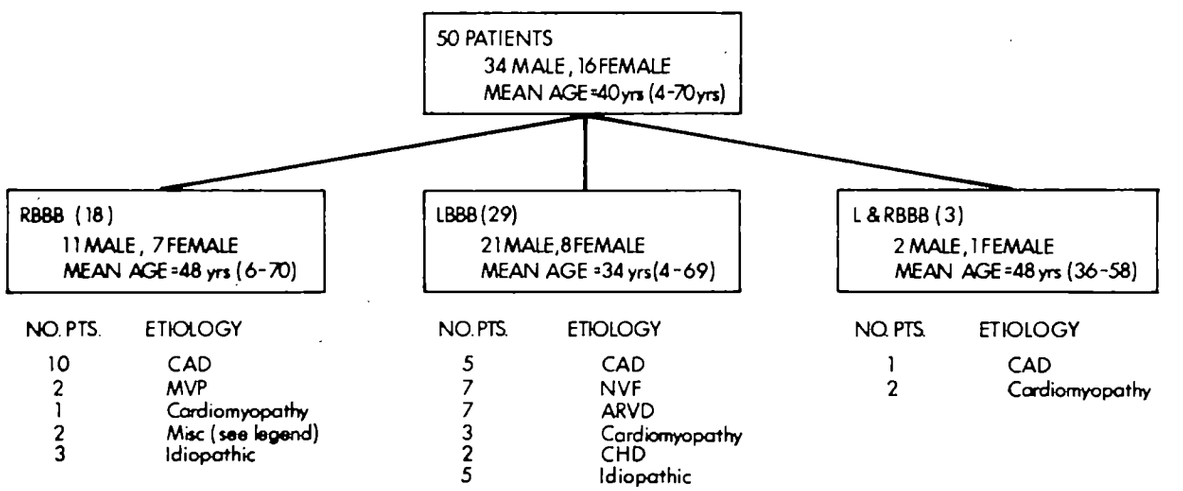

**FIGURE 1.** Tachycardia morphology and distribution of etiologies in 50 patients with recurrent VT. One patient with VT with an RBBB morphology had a left ventricular aneurysm of uncertain cause and another had a catecholamine-related tachycardia. ARVD = arrhythmogenic right ventricular dysplasia; CAD = coronary artery disease; CHD = congenital heart disease; MVP = mitral valve prolapse; NVF = nodoventricular fiber.

* Underlying rhythm was atrial flutter-fibrillation. † During isoproterenol infusion.

CL = cycle length; CS = coronary sinus; ECG = electrocardiogram; $\epsilon$ = epsilon potential; IRBBB = incomplete right bundle branch block; IVCD = intraventricular conduction delay; LAE = left atrial enlargement; LV = left ventricle; MI = myocardial infarction; N = normal; NA = not available; PS = programmed stimulation; QRSM = QRS morphology; RA = right atrium; RV = right ventricle; RVA = right ventricular apex; RVOT = right ventricular outflow tract.

electrophysiologic criteria.[19] Tachycardia using the nodoventricular fiber in the anterograde direction exhibited features suggestive of VT including the following: wide QRS tachycardia with LBBB morphology (7 patients), absence of a His deflection preceding the QRS complexes during tachycardia (7 patients), and ventriculoatrial dissociation during tachycardia (3 patients). Tachycardia could be frequently induced or terminated by premature atrial stimuli or rapid atrial pacing (Table II).

Six patients remain well and free of sustained symptomatic tachycardia on medical therapy (mean follow-up 30 ± 17 months). One patient, a 4-year-old boy, had been treated with quinidine, initially with a dose that was therapeutic. During his growth this dose became inadequate and he developed recurrent tachycardia. Since his dosage was adjusted, he has had no tachycardia.

**Patients with arrhythmogenic right ventricular dysplasia:** Seven patients were felt to have arrhythmogenic right ventricular dysplasia.[20] Four patients had had serious symptoms in association with their arrhythmia and 5 patients had required multiple cardioversions. Five patients had symptoms predominantly or exclusively associated with exercise or activity.

Associated cardiac disease was unusual. There was no obvious familial association but 1 patient had a family history of sudden death and another had a sibling with exercise-induced VT. Patients with arrhythmogenic right ventricular dysplasia had no distinctive physical findings, although 1 patient presented with right ventricular failure. Chest x-rays were typically normal and electrocardiographic features during sinus rhythm were nonspecific (Fig. 3, top left): low voltage in the limb leads (4 patients), T-wave inversion in the right precordial leads (7 patients), nonspecific intra-

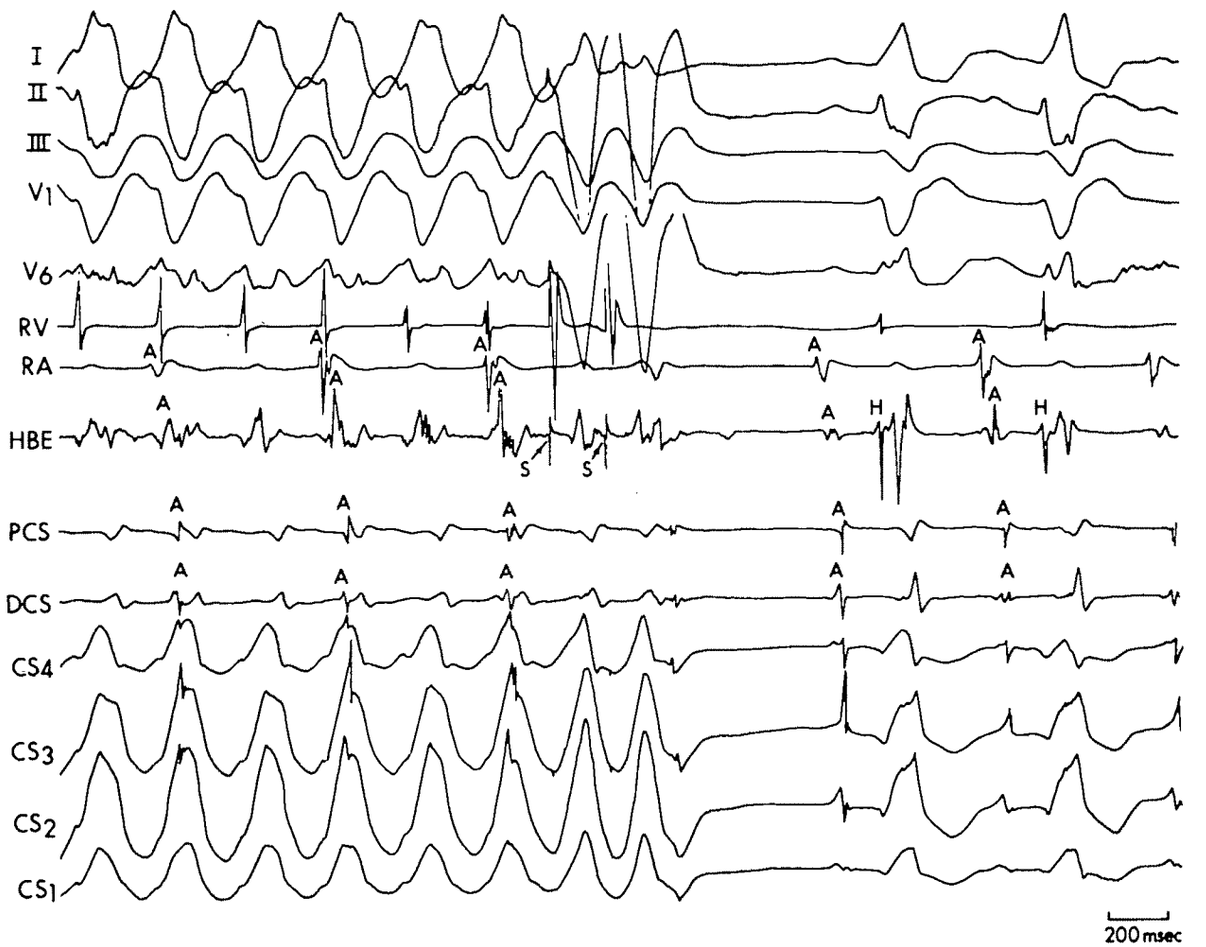

**FIGURE 2.** Patient 2. Termination of reciprocating tachycardia in a patient with a nodoventricular fiber. Recordings from **top** to **bottom** include standard electrocardiographic leads I, II, III, $V_1$, and $V_6$; bipolar electrograms recorded from the right ventricular apex (RV), the right atrium (RA), the region of the His bundle (HBE), the proximal coronary sinus (PCS), and the distal coronary sinus (DCS); and unipolar electrograms recorded from the proximal ($CS_4$) to the distal ($CS_1$) coronary sinus. Initially, tachycardia with an LBBB morphology is present. No His electrogram is visible before the QRS complexes and there is complete ventriculoatrial dissociation. After 7 beats of tachycardia, 2 successive ventricular premature depolarizations are introduced, resulting in conversion to sinus rhythm. The morphologies of the ventricular complexes in sinus rhythm are similar to those during the tachycardia and show varying degrees of LBBB aberration; in addition, the His deflection occurs after the onset of the surface QRS complex.

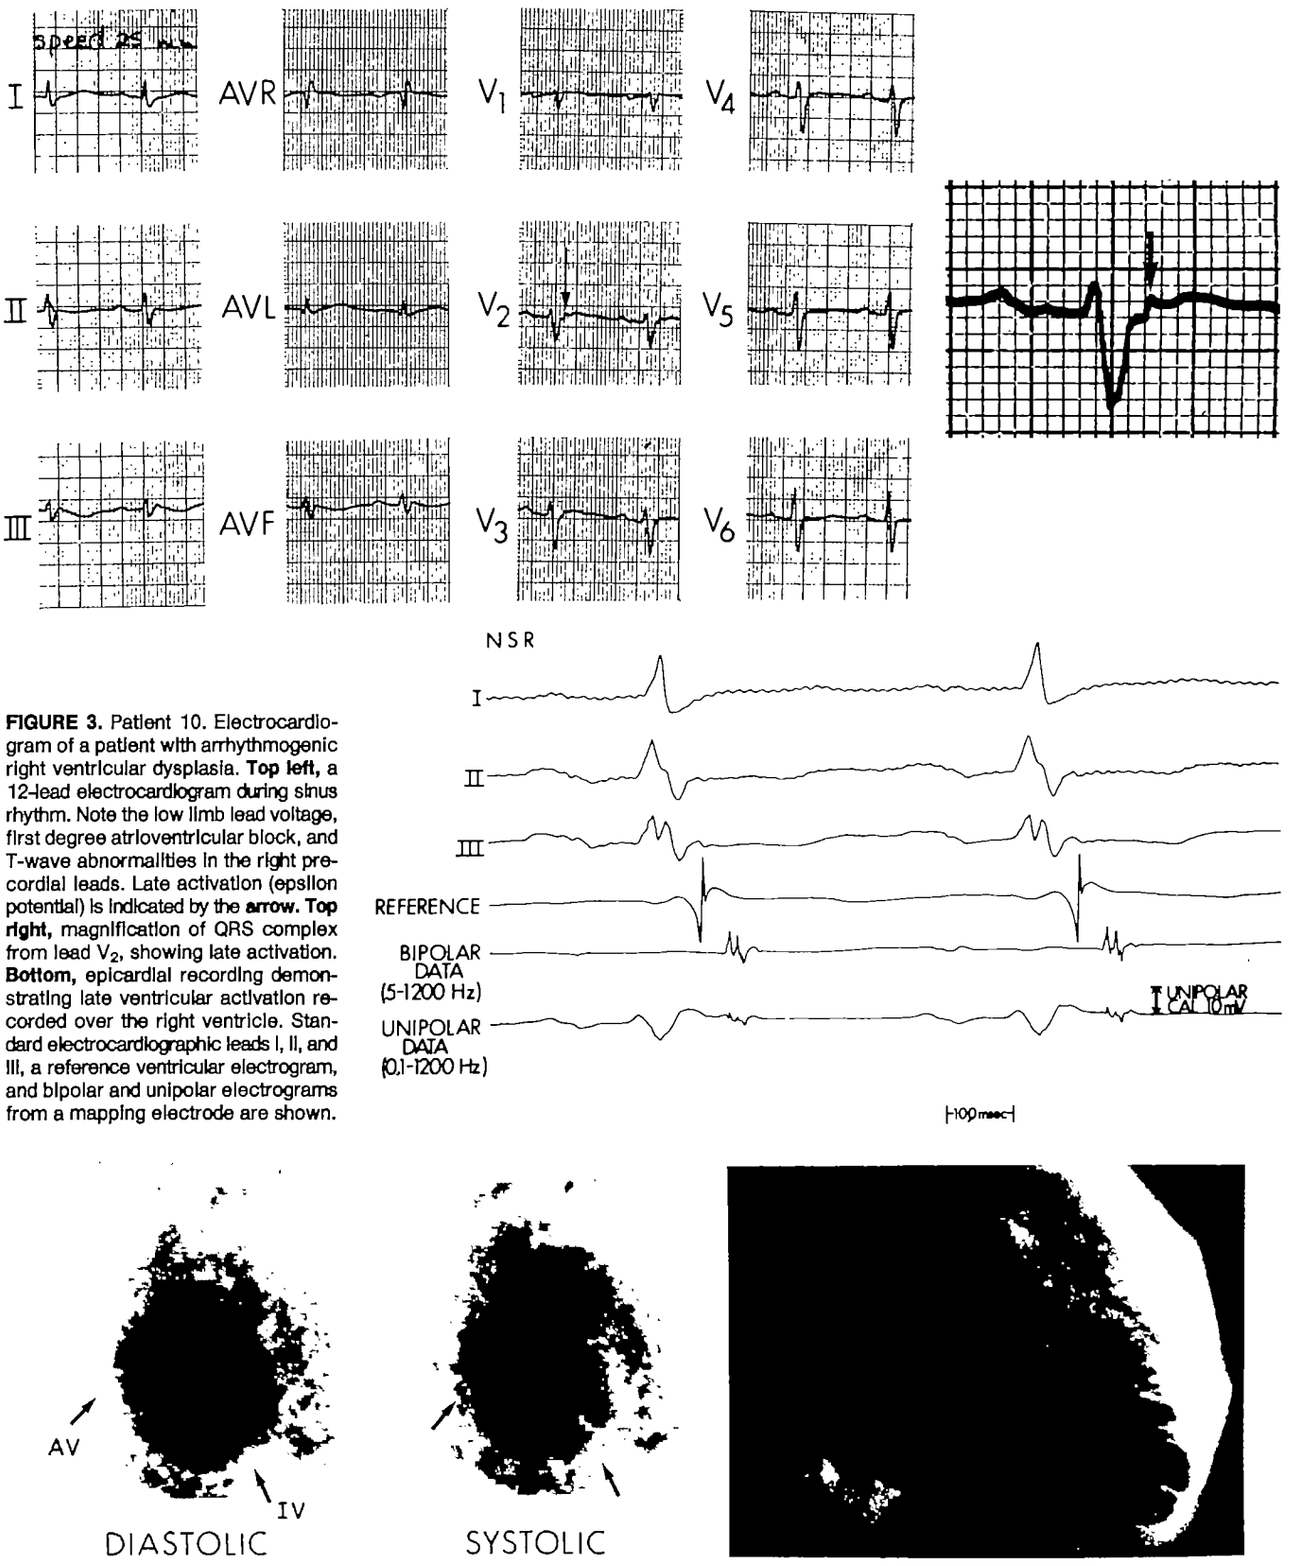

**FIGURE 3.** Patient 10. Electrocardiogram of a patient with arrhythmogenic right ventricular dysplasia. **Top left,** a 12-lead electrocardiogram during sinus rhythm. Note the low limb lead voltage, first degree atrioventricular block, and T-wave abnormalities in the right precordial leads. Late activation (epsilon potential) is indicated by the **arrow. Top right,** magnification of QRS complex from lead $V_2$, showing late activation. **Bottom,** epicardial recording demonstrating late ventricular activation recorded over the right ventricle. Standard electrocardiographic leads I, II, and III, a reference ventricular electrogram, and bipolar and unipolar electrograms from a mapping electrode are shown.

**FIGURE 4.** Patient 12. Comparison of radionuclide angiograms and a cineangrogram in a patient with arrhythmogenic right ventricular dysplasia. **Left,** multigated radionuclide angiograms taken in the left anterior oblique view with 45° of caudal inclination of the camera, end-diastolic and end-systolic frames. The **arrows** indicate the plane of the interventricular septum (IV) and the atrioventricular groove (AV). The right ventricle is markedly enlarged and hypokinetic (ejection fraction 15%). The left ventricle is normal in size and function (ejection fraction 74%). **Right,** cineanglogram, posteroanterior view. The right ventricle is enlarged and hypokinetic, and there are akinetic segments of the apex, diaphragmatic surface, and outflow tract. Delay is evident in the emptying of the right ventricle along the inferior border, with stagnation of contrast material.

ventricular conduction delay (4 patients), and first-degree block (1 patient). The electrical axis was normal in all patients. Only 1 patient showed evidence of delayed depolarization (epsilon potential)[21] on the standard electrocardiogram (Fig. 3).

Despite the lack of characteristic clinical features, noninvasive evaluation frequently suggested right ventricular abnormalities in these patients. In 5 of the 6 patients who had echocardiographic studies (Table III), the right ventricular chamber appeared enlarged and hypokinetic. The left ventricles appeared normal in all patients. Only 1 patient, who only had an M-mode study, had a normal echocardiogram.

Dramatic right ventricular enlargement and hypokinesia were seen in the 3 patients who underwent radionuclide study (Fig. 4, left). Right ventricular ejection fractions were estimated at <30% for the 3 patients who had left ventricular ejection fractions of 58, 74, and 70%, respectively. In 1 patient, focal right ventricular wall motion abnormalities were also detected by radionuclide angiography.

With right ventricular angiography, all of these patients demonstrated global dysfunction and enlargement of the right ventricle in addition to localized right ventricular dyskinesia or diverticula of the right ventricular wall (Fig. 4). Localized abnormalities of the right ventricular wall were frequently multiple. Despite the angiographic abnormalities, right-sided hemodynamic function was typically normal. Only 2 patients had modest elevation of the right ventricular end-diastolic pressure (16 mm Hg in both).

Findings on left ventricular angiography were normal in 4 patients, with 3 having only minor wall motion abnormalities of the left ventricle. Left ventricular end-diastolic pressure was normal in all patients and none had significant coronary artery disease.

All but 1 patient with arrhythmogenic right ventricular dysplasia underwent electrophysiologic study. Initiation of VT by programmed right ventricular stimulation was possible in 4 of the 6 and could be terminated by right ventricular pacing in both patients in which it was sustained.

Endocardial and intraoperative mapping during VT localized the site of earliest ventricular activation to the right ventricle in all 6 patients. In the 2 patients who underwent intraoperative mapping, late activation (Fig. 3, bottom) and low amplitude, fragmented potentials were present over extensive portions of the right ventricle. Activation of the left ventricle appeared normal.

Five patients were treated medically and 2 underwent surgery: 1 patient underwent cryoablation of an ectopic focus,[22] and in the other a large portion of the right ventricle was isolated by an encircling endocardial ventriculotomy.[23] One patient (Patient 9) treated with quinidine died suddenly 19 months after evaluation,

**TABLE III Angiographic, Echocardiographic, and Radionuclide Angiographic Findings in Patients With Arrhythmogenic Right Ventricular Dysplasia**

DIAPH = diaphragmatic surface; EF = ejection fraction; INF = infundibulum; LV = left ventricle; MR = mitral regurgitation; MVP = mitral valve prolapse; RV = right ventricle.

although she was shown to have therapeutic serum quinidine levels at the time of death. The remaining 6 patients were alive and well at follow-up (mean 14 months, range 2 to 42.)

**Patients with coronary artery disease:** Five male patients (45 to 67 years of age, mean 56) had coronary artery disease. Two patients had had serious symptoms associated with VT and all had required multiple cardioversions. Angiography confirmed the presence of a left ventricular aneurysm in all patients.

The electrocardiogram indicated prior myocardial infarction in all 5 patients and 3 showed persistent S-T segment elevation, suggesting the presence of a ventricular aneurysm.

Four of the 5 patients had inducible sustained VT. Intraoperative mapping showed that VT originated in the interventricular septum bordering the aneurysm in 4 patients. The fifth patient underwent catheter endocardial mapping which was consistent with a left ventricular origin of the tachycardia.

Four patients were treated surgically. Two underwent an encircling endocardial ventriculotomy as described by Guiraudon et al[24] and 2 underwent endocardial resection. There was 1 perioperative death. Three patients were alive and without clinical recurrence 2, 12, and 16 months postoperatively. One patient with congestive failure and progressive glomerulonephritis was treated medically and died within 1 month of evaluation.

**Patients with biventricular cardiomyopathy:** Three patients were found to have a biventricular cardiomyopathy. Symptoms in these patients were primarily related to episodes of VT. Two of the 3 had had syncope. Symptoms of left ventricular failure were not prominent in any of the 3. All 3 patients underwent cineangiography of the right ventricle and had localized right ventricular contraction abnormalities, but no patient was observed to have sacculations or diverticula of the right ventricle. Two patients had normal coronary angiograms; the third patient, a 16-year-old girl, did not undergo coronary angiography.

Endocardial mapping during tachycardia demonstrated ventricular activation to be earliest in the right ventricle in 2 patients. One patient (Patient 21) was also mapped intraoperatively. The earliest area of activation was located in the right ventricular outflow tract.

One patient underwent surgical cryoablation of the site of origin of the VT with additional encircling transmural ventriculotomy. She remains well and free of arrhythmia 22 months after surgery. One medically treated patient had progressively more frequent episodes of recurrent VT despite aggressive antiarrhythmic therapy and died suddenly 25 months after initial evaluation. The other medically treated patient was alive and well at follow-up.

**Patients with congenital heart disease:** Two male patients had congenital heart disease; 1 had Ebstein's anomaly and the other had undergone complete surgical repair of tetralogy of Fallot 15 years previously. Neither had significant hemodynamic abnormalities. The patient with Ebstein's anomaly had had syncope and hypotension during VT. Both had required cardioversion.

Both patients had VT that could be induced. Earliest activation was recorded from the right ventricle in both patients. Both patients have been free of sustained recurrent tachycardia on medical therapy alone, at 16 and 39 months after evaluation.

**Patients without organic heart disease:** In 5 patients, 3 male and 2 female (20 to 52 years old, mean 35), no cause of tachycardia could be demonstrated. Only 1 of these 5 patients had had serious symptoms in association with the tachycardia; none had required cardioversion. All 5 patients had normal left ventriculograms, no significant coronary artery disease, and right ventriculograms that were considered normal.

VT could be induced in only 2 of the 5 patients. Limited endocardial activation mapping was carried out in 3 patients during tachycardia and in 1 patient during a period when frequent premature ventricular contractions occurred. Earliest ventricular activation occurred in the right ventricle in 3 patients and in the region of the His bundle catheter in 1 patient.

All 5 patients have received medical therapy. Mean follow-up has been 12 months (range 2 to 33). Four patients have had no sustained tachycardia. One patient has had a recurrence of VT about every 6 months.

## Discussion

The present study describes the findings in 29 patients with tachycardia exhibiting exclusively an LBBB morphology. More than 80% had an associated cardiac abnormality. This finding differs from those in other studies[9,10] in which idiopathic ventricular tachycardia was more common in patients exhibiting LBBB configuration than in patients whose VT had RBBB morphology. The reason for this difference is uncertain, but no cases of arrhythmogenic right ventricular dysplasia or nodoventricular fibers were reported in the other series. Since both may be mistaken for idiopathic VT in the absence of right ventriculography or electrophysiologic study, the difference may be related to the nature of the diagnostic evaluation in previously reported series. We routinely performed right heart angiography and complete electrophysiologic study in these patients. Alternatively, the discrepancy may be due to differences in case selection. Our referral population tends to select patients with uncertain cause and management difficulty. Thus, the proportion of patients with arrhythmogenic right ventricular dysplasia and nodoventricular fibers in the present study may be high and not representative for an unselected population of patients with VT having LBBB morphology.

Patients with nodoventricular fibers were included in this study because the reentry tachycardia mimicked VT. Indeed, these patients were often referred with a presumptive diagnosis of VT. The presence of LBBB morphology, indicating preexcitation of the right ventricle, was observed intermittently during sinus rhythm in 5 of 7 and consistently during tachycardia in 7 of 7 patients. No patient with a nodoventricular fiber preexciting the left ventricle has been seen in over 400 cases of preexcitation studied in this laboratory. Thus, the presence of a Mahaim fiber should be considered and excluded in the setting of a tachycardia having LBBB morphology, especially if the QRS complexes

during sinus rhythm show varying degrees of apparent LBBB aberration.

Arrhythmogenic right ventricular dysplasia was diagnosed in 7 patients. This cardiomyopathy primarily involves the right ventricle and was first characterized by Fontaine et al.[25] In their studies as well as in the present study, the disorder exhibited no distinctive clinical or electrocardiographic characteristics. The lack of characteristic clinical features and the presence of normal chest x-rays and left ventricular angiograms suggested an idiopathic VT in the absence of any further evaluation. The diagnosis can be made by right ventricular angiography. Echocardiography and radionuclide angiography were also seen to be sensitive in detecting isolated abnormalities of the right ventricle. These techniques may be useful for noninvasive screening and follow-up of these patients.

Diagnosis of the underlying disease in patients manifesting tachycardia with an LBBB morphology has prognostic and therapeutic implications. Patients with nodoventricular fibers were usually without serious symptoms, had a relatively benign course, and were responsive to medical management. In contrast, the diagnosis of arrhythmogenic right ventricular dysplasia may be associated with serious symptoms and sudden death. The severity and frequency of symptoms in patients with arrhythmogenic right ventricular dysplasia varied widely, but there was no apparent relation between the severity of the arrhythmia and the degree of angiographic abnormality. The course of the process was also variable and no patient with a clearly progressive course has been identified. However, the observation that all of these patients have had serious associated symptoms or cardioversion and the sudden death of a 14-year-old child 19 months after diagnosis indicated that this disorder is not benign.

Most of our patients with arrhythmogenic right ventricular dysplasia have been managed medically. The potential for surgical therapy in medically refractory persons with this condition was confirmed in 2 of our patients.[26] In 1, VT with a different morphology reemerged 23 months after successful cryoablation surgery. Thus, it is possible that a new focus of VT may appear after successful surgical therapy.

Patients with coronary artery disease and biventricular cardiomyopathy had, as expected, significant mortality. Patients without apparent organic heart disease had a good prognosis and rarely had serious associated symptoms.

We conclude that for the referred population of patients with recurrent symptomatic VT, tachycardia originating from the right ventricle is not uncommon and is usually associated with organic heart disease. Prognosis depends on the underlying organic disease but serious symptoms occur often and characterization of right ventricular tachycardia as benign are unjustified. Electrophysiologic studies and right ventricular cineangiography are helpful in the complete evaluation of these patients.

## Addendum

Since submission of this report, 2 of our medically treated patients with arrhythmogenic RV dysplasia have had surgical exclusion of the entire free wall of the right ventricle, with good results.

# Electrophysiologic Studies in Atrial Fibrillation

## Slow Conduction of Premature Impulses: A Possible Manifestation of the Background for Reentry

FRANCISCO G. COSIO, MD, JOSÉ PALACIOS, MD, JOSÉ M. VIDAL, MD, EMILIO G. COCINA, MD, MIGUEL A. GÓMEZ-SÁNCHEZ, MD, and LUIS TAMARGO, MD

**Extrastimulus-induced intraatrial conduction delays were measured in 12 patients with documented episodes of atrial fibrillation (AF) by recording atrial electrograms at the high right atrium, His bundle region, and coronary sinus. Seventeen patients with and without heart disease, but without atrial arrhythmias served as the control group. During baseline-paced atrial rhythms, a conduction delay zone could be delineated, near the atrial effective refractory period, during which all extrastimuli produced conduction delays. When compared at the same paced cycle lengths (500 to 650 ms), the patients with AF had shorter atrial effective refractory periods (mean ± standard deviation 206 ± 24.1 versus 233 ± 28.2 in control patients, $p < 0.02$), wider conduction delay zones (79 ± 21.7 ms versus 52 ± 21 in control patients, $p < 0.01$), and longer conduction delays both to the His bundle region (64 ± 18.3 ms versus 35 ± 21.7 in control patients, $p < 0.005$) and the coronary sinus (76 ± 18.9 ms versus 35 ± 16.1 in control patients, $p < 0.001$). Repetitive atrial responses were recorded in 6 patients with AF and in 9 control subjects. Sinus nodal function abnormalities were detected in 6 of the patients with fibrillation.**

**Patients with AF had a higher tendency than control subjects to develop slow intraatrial conduction, as well as shorter effective refractory periods. Since both features would favor reentry, they may be the electrophysiologic manifestations of the abnormalities making these patients prone to atrial reentrant arrhythmias. Repetitive atrial responses were of no predictive value. Sinus nodal dysfunction was frequently found, but was not essential for the occurrence of AF.**

The sustained electrical activity that characterizes flutter and fibrillation has been the object of continuous interest and research. The self-sustaining character of these arrhythmias has been explained mainly through reentrant mechanisms,[1,2] although a role of abnormal automaticity in its precipitation and maintenance has been suggested.[3–5]

Animal experiments have repeatedly confirmed the possibility of sustaining atrial flutter through a reentrant mechanism; in all of these experiments a conduction disturbance was essential in the mechanism. In some cases, conduction was disturbed by anatomic lesions,[6–8] in others by stimulation during in complete recovery of excitability of the myocardium.[8–10] Differences in the timing of recovery of excitability of adjacent areas were shown to cause unidirectional block, setting the grounds for a continuous circular movements of the propagated impulse.

AF has also been explained as an alteration of impulse conduction. Further dispersion of the recovery of excitability, creating more marked desynchronization of adjacent areas of myocardium, would break the activation fronts into multiple wavelets that could perpetuate themselves as continuous irregular atrial activation, given a large enough mass of tissue and a short enough refractory period.[1,2,8] The continuous and erratic spread of excitation in multiple crisscrossing patterns would be the basis for further dispersion of the recovery of excitability, and thus should tend to sustain

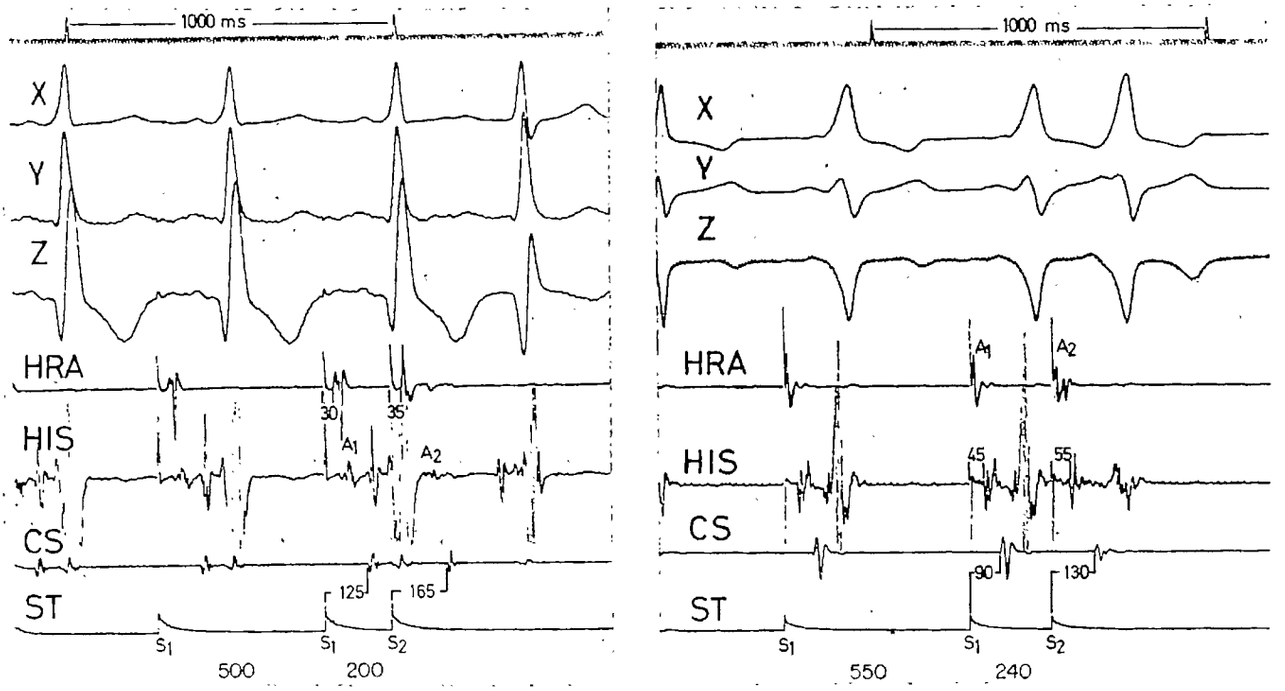

**FIGURE 1.** Effect of early extrastimuli on intraatrial conduction. Measurements of $S_1$-$A_1$ and $S_2$-$A_2$ intervals are shown. **Left panel,** an extrastimulus with a 200 ms $S_1$-$S_2$ interval, over a basic paced cycle length of 500 ms, prolongs intraatrial conduction from 30 to 35 ms in the high right atrium (HRA) and from 125 to 165 ms in the coronary sinus electrogram (CS). The atrial deflection of the His bundle electrogram (HBE) becomes slurred and of low amplitude, and no reliable measurement can be made of the $S_2$-$A_2$ interval here. ST = stimulator output. **Right panel,** the basic cycle length is 550 ms. An extrastimulus with an $S_1$-$S_2$ interval of 240 ms increases conduction time to the HIS and the CS, and the HRA $A_2$ shows a "double" deflection. All values in milliseconds.

the arrhythmia. On the other hand, a prolongation of the refractory period tended to terminate the arrhythmia, through a progressive synchronization of the activation of adjacent areas of muscle.[1,2,8–10]

The onset of clinical human flutter and fibrillation may also be related to slow conduction of impulses through partly recovered myocardium. Rapid stimulation of the myocardium, or rapid repetitive firing at a point of stimulation, may induce enough conduction delay and dispersion of the recovery of excitability to precipitate sustained flutter or fibrillation.[11,12]

The role of normal pacemaker function in the induction and maintenance of AF is probably complex. AF is common in the sick sinus syndrome,[13,14] and pathologic examination of the sinus node in patients with AF shows a high incidence of abnormalities.[15,16] It has been postulated that bradycardia may induce an increase in the dispersion of excitability recovery and thus facilitate reentrant arrhythmias,[16,17] and that AF may be a manifestation of sinus nodal dysfunction. On the other hand, it has been shown that experimental AF is easier to sustain if normal pacemaker function continues.[18]

The application of clinical electrophysiologic techniques to the study of atrial flutter and fibrillation has not clearly defined the features that may characterize a propensity to develop these arrhythmias spontaneously. AF can be produced in normal subjects by atrial stimulation, but usually as a short-lived nonsustained episode.[19] Repetitive atrial responses may also be induced by atrial extrastimuli; their appearance has been considered an expression of "atrial vulnerability," and even a sign of a predisposition to atrial flutter or fibrillation.[20,21] However other clinical and experimental evidence supports the concept that repetitive atrial responses are a nonspecific phenomenon.[8,9,22,23]

The atrial effective refractory period has been measured by several investigators in patients with atrial flutter or fibrillation; while some describe a tendency to short values,[20] others have found no significant deviations.[12,24,25] The degree of dispersion of the recovery of excitability has been explored by measuring atrial effective refractory periods in different points of the right atrium[20] and in both atria,[25] but no significant results have been obtained in atrial flutter or fibrillation. The work of Simpson et al[26] (published only in abstract form) suggests that slow conduction of premature impulses in patients with prolonged P-wave duration may be related to the pathogenesis of AF; however, a direct relation was not shown in their results.

With this background in mind, our study was prospectively designed to analyze the electrophysiologic properties of the atrium and sinus node in patients with documented episodes of AF. Specifically, we addressed the following questions: (1) What are the features of intraatrial conduction during premature stimulation? (2) What is the duration of the atrial refractory period? (3) What is the significance of repetitive responses? (4) What is the role of sinus nodal dysfunction?

## Methods

**Patient population:** The study group consisted of 12 patients with AF. The arrhythmias were paroxysmal in all but Patient 4, who was studied after cardioversion of fibrillation that was sustained for several months. Ages ranged from 25 to 72 years (mean ± standard deviation 55.5 ± 12.7). Associated arrhythmias included sinus bradycardia or sinus arrest in 3 and reentrant tachycardias related to the Wolff-Parkinson-White syndrome in 2. Associated cardiovascular diseases were hypertension (2 patients), coronary artery disease with angina (1 patient), hypertrophic obstructive cardiomyopathy (1 patient), and chronic obstructive pulmonary disease (1 patient). Two (Patients 6 and 8) had mild elevations of thyroid hormone levels in the serum.

The control group consisted of 17 patients with and without organic heart disease or associated arrhythmias, but without a history of atrial flutter or fibrillation. Their ages ranged from 19 to 73 years (mean 49 ± 18). Associated rhythm abnormalities were sinus bradycardia in 6, manifest or concealed Wolff-Parkinson-White syndrome with reentrant atrioventricular tachycardia in 2, ventricular tachycardia in 3, and reentrant nodal tachycardia in 1. One patient had hypertrophic cardiomyopathy, 3 had coronary artery disease, and 1 had an atrial septal defect. Only 2 of the control patients were normal subjects.

**Electrophysiologic studies:** Informed consent was obtained from the patients for the performance of the studies. All cardioactive medications were discontinued at least 3 days before the procedure. The patients were fasting and lightly sedated with oral diazepam. Under local anesthesia, quadripolar catheter-electrodes with a 1-cm interelectrode distance were advanced to the right atrial appendage from the femoral vein, and to the middle or distal coronary sinus from the arm. Stimulation of the right atrium was performed through the distal pair of electrodes in the right atrial catheter. Bipolar recordings were obtained from the high right atrium through the proximal pair of electrodes of the same catheter, and from the left atrium through the distal pair of the coronary sinus catheter. A His bundle electrogram was recorded with the 2 distal electrodes of a tripolar catheter-electrode, or with a bipolar catheter electrode; in either case interelectrode distance was 1 cm. Stimulation was performed with square impulses 2 ms in duration, and intensity twice threshold, delivered by a programmable stimulator (Medtronic 5325).

The intracardiac signals were filtered to record frequencies of 40 to 500 Hz. Recordings were made on a photographic (DR-12, Electronics for Medicine) or ink-jet (Elema) recorder, at a speed of 100 mm/s with simultaneous inscription of leads X, Y, and Z of the orthogonal Frank system.

**Measurements and terms:** The P wave was measured from the simultaneous, high gain X, Y, and Z leads recorded at 100 mm/s. Intervals to and from the intracardiac potentials were taken at their onset, marked by the first sharp deflection taking off from the baseline. This was usually easy to recognize in the coronary sinus and high right atrial electrograms; however, after the application of early extrastimuli the atrial deflection of the His bundle electrogram was occasionally so slurred as to make it difficult to recognize its onset, and in these cases the measurement was omitted (Fig. 1, left panel). When premature stimulation resulted in a split or double atrial deflection, measurements were taken to the onset of the first part of the deflection (Fig. 1, right panel). The difficulty in locating the intrinsecoid deflection after some extrastimuli was the main reason to use the onset of the electrograms for timing, even though this may have underestimated intraatrial conduction time by recording some distant electrical activity.

$A_1$ and $S_1$ refer to the atrial deflection and the driving stimulus of the basic rhythm. $S_2$ and $A_2$ refer to the extrastimulus and the atrial deflection resulting from it, when the basic rhythm is paced. S refers to an extrastimulus delivered on a spontaneous atrial rhythm. The *atrial effective refractory period* is the longest $A_1$-S or $S_1$-$S_2$ interval not resulting in capture by S or $S_2$. *Atrial conduction delay* was the increase in S-$A_2$ or $S_2$-$A_2$ observed with early premature beats, when compared with late premature beats. *Conduction delay zone* was the range of extrastimuli producing atrial conduction delay in any of the sites explored. *Atrial repetitive responses* were defined as the appearance of 2 or more atrial complexes at intervals shorter than 300 ms in all atrial electrograms, in response to 1 extrastimulus.

*Sinus nodal recovery time* was measured after atrial pacing during 1 minute at cycle lengths of 600, 460, and 375 ms, the longest value being reported. A corrected recovery time longer than 525 ms was considered abnormal.[27] *Secondary pauses*

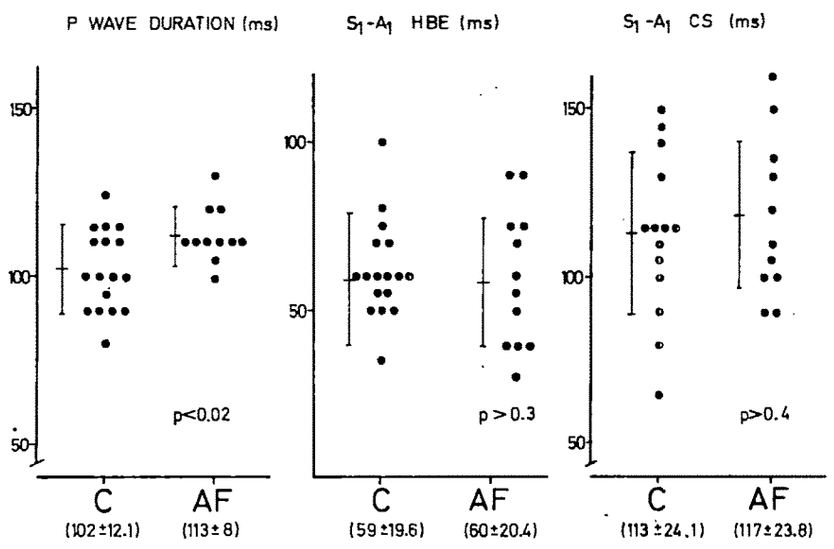

**FIGURE 2.** Graphic representation of P-wave duration and basal conduction time of the atrial stimuli ($S_1$-$A_1$) to the His bundle electrogram (HBE) and the coronary sinus (CS) electrogram. The **vertical bars** represent mean ± 1 standard deviation. AF = patients with atrial fibrillation; C = control group. Values in milliseconds.

were defined as those occurring after the second beat after recovery, and having a duration at least 40% longer than the basic cycle length.[28] *Sinoatrial conduction time* was estimated by Strauss's method, and a noncorrected value of 260 ms or longer was considered abnormal.[29]

The results are expressed as the mean ± 1 standard deviation. The statistical significance of the differences was analyzed by Student's *t* test for unpaired values.

## Results

The electrophysiologic findings are summarized in Table I.

**Intraatrial conduction:** P-wave duration was significantly longer in the study group (113 ± 8 ms) than in control subjects (102 ± 12.1, $p < 0.02$), but the 2 groups overlapped to a large extent (Fig. 2). Intraatrial conduction of nonpremature stimuli ($S_1$-$A_1$ interval) to the His bundle region and to the coronary sinus was not different in either group (Fig. 2). This interval was the same as that for the extrastimuli (S-$A_2$ or $S_2$-$A_2$) during most of the cardiac cycle. However, S-$A_2$ and $S_2$-$A_2$ prolongation tended to occur when the atrial effective refractory period was approached (Fig. 3), defining a conduction delay zone. In 2 patients of the study group (Patients 6 and 8), shortening of the S-$A_2$ or $S_2$-$A_2$ occurred in some recording sites, even though other sites might have shown a conduction delay for the same extrastimulus (Fig. 3 and 4).

During sinus rhythm, the conduction delay zone was almost always very short or undectable, and the atrial conduction delays were minimal to all recording sites (Fig. 3, 5). However, during atrial paced rhythms, both atrial conduction delays and conduction delay zones increased markedly and could be easily measured (Fig. 3). Minimal changes in rate by atrial pacing caused marked increases in atrial conduction delays and conduction delay zone duration, while further rate increases produced generally fewer changes, and in variable directions (Fig. 5). The degree of atrial conduction delay to the various recording sites was quite different (Fig. 3, Table I).

For the comparison between both groups we used only the results obtained at paced cycle lengths of 500 to 650 ms. The patients with AF had wider conduction

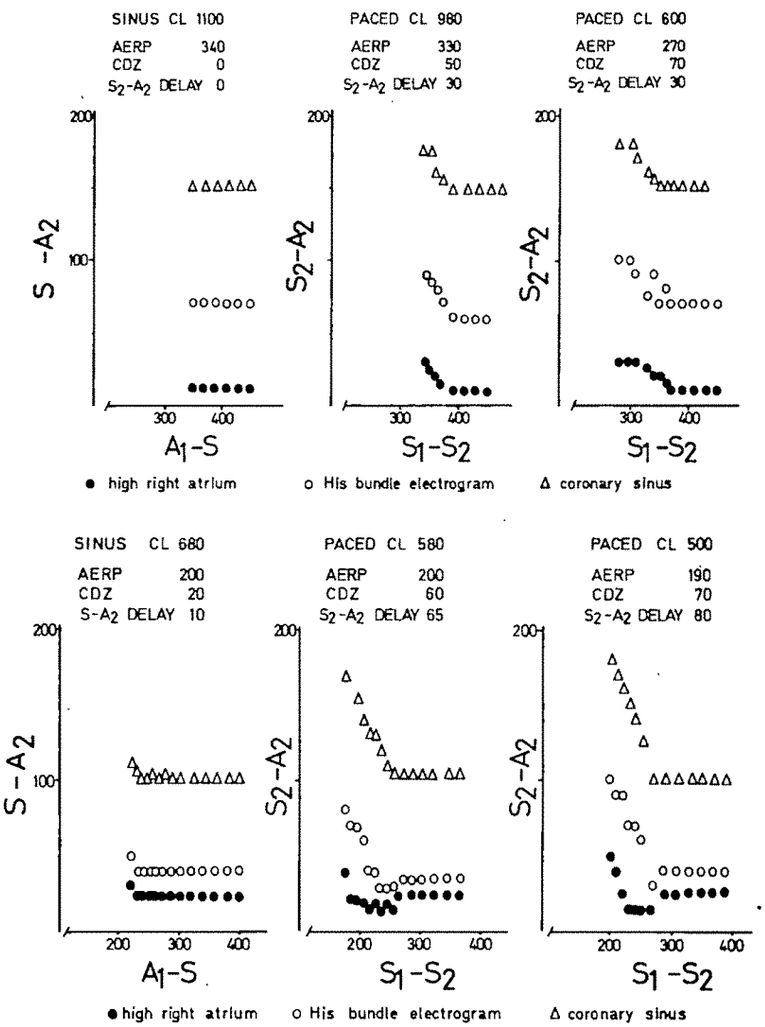

**FIGURE 3.** Graphic representation of the changes in $S_2$-$A_2$ with increasing prematurity of $S_2$. **Top panel,** Patient 8 of the control group. Basal intraatrial conduction is long, but extrastimulus-induced atrial conduction delay is small. **Bottom panel,** Case 5 of the study group. Despite a much shorter intraatrial conduction time basally, extrastimulus-induced conduction delays are much longer. This patient also showed some shortening of the $S_2$-$A_2$ intervals to the high right atrium and the His bundle electrograms that were simultaneous with delays to the coronary sinus electrogram. AERP = atrial effective refractory period; CDZ = conduction delay zone; CL = cycle length; $S_2$-$A_2$ delay = atrial conduction delay. Values in milliseconds.

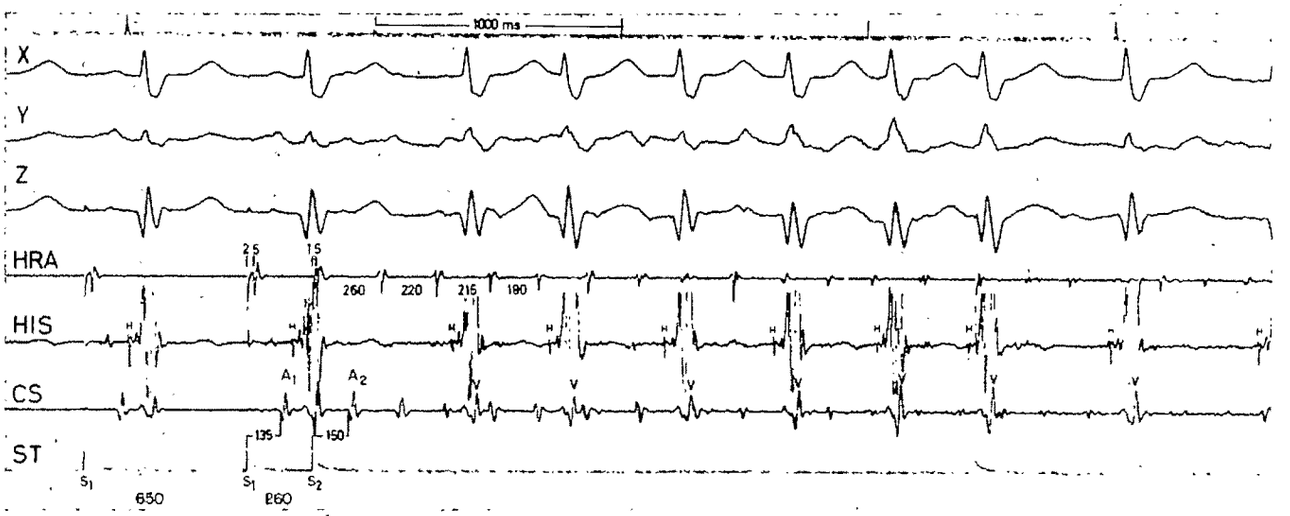

**FIGURE 4.** Precipitation of AF with 1 extrastimulus in Patient 7 of the study group. $S_2$ produces a conduction delay to the coronary sinus (CS) and slight shortening of conduction time to the high right atrium (HRA). $S_2$-$A_2$ is not measurable to the His bundle electrogram (HBE). Multiple atrial responses follow, with irregular intervals of <300 ms. The arrhythmia was sustained and was terminated by direct-current cardioversion 20 minutes later. Values in milliseconds.

delay zones (79 ± 21.7 ms versus 52 ± 21 in control patients, $p < 0.01$) (Fig. 6), and longer maximal conduction delays, both to the His bundle electrogram (64 ± 18.3 ms versus 35 ± 21.7 in control patients, $p < 0.005$) and to the coronary sinus (76 ± 18.9 ms versus 35 ± 16.1 in control patients, $p < 0.001$) (Fig. 7). The correlation of P-wave duration with the maximal atrial conduction delay observed was weak ($r = 0.3$).

**Atrial effective refractory period:** At the same paced cycle lengths of 500 to 650 ms, the atrial effective refractory period was shorter in the patients with AF (206 ± 24.1 ms than in the control subjects (233 ± 28.2 ms, $p < 0.02$) (Fig. 6). The difference was still significant when the comparison was made at cycle lengths of 500 to 600 ms (both spontaneous and paced): study group, 209 ± 20.9 ms, versus control group, 238 ± 26.7 ($p < 0.02$).

**Repetitive atrial responses:** Repetitive responses were observed mainly during the conduction delay zone, at paced cycle lengths of 800 to 400 ms. Only 1 patient (Patient 8, study group) developed repetitive responses on a basic sinus rhythm, during a "superconduction" zone, in which the $S$-$A_2$ interval decreased to a variable extent in all 3 electrograms. In the study group, 6 of 10 patients studied at paced basic cycle lengths of 500 to 650 ms developed repetitive responses. This incidence was similar to that in the control group at the same cycle lengths (8 of 14 patients).

Repetitive responses led to AF in 2 patients (Patients 8 and 11 of the study group). The stimulus leading to AF in Patient 8 showed shortened conduction time to the high right atrium, and prolonged conduction time to the His bundle and coronary sinus electrograms (Fig. 4).

**Sinus nodal function in patients with AF:** Corrected sinus nodal recovery time was prolonged over 525 ms in 3 patients, and another patient had secondary sinus pauses. Sinoatrial conduction time was longer than 260 ms in 4 patients. A total of 6 patients (50%) had abnormal sinus nodal function by these parameters. The dysfunction was clinically significant in 2 patients with bradycardia-related syncope or near-syncope (Patients 10 and 12) and in Patient 11, who developed sinus arrest after cardioversion.

## Discussion

The study of intraatrial conduction of premature stimuli in this group of patients with AF showed a marked tendency to slow propagation, both in terms of an increase in conduction delay in several directions, and of a wider time zone during which the early premature impulses were slowly conducted. The overlap with the control group might have been reduced if these later patients had been normal; however, variation in electrophysiologic features might be expected in patients with a history of AF, given the importance of functional neurologic factors[30,31] as well as the various underlying anatomic substrates.[13]

The correlation of basal intraatrial conduction, as expressed by P-wave duration, with extrastimulus-induced conduction delays was weak. The slow conduction of early extrastimuli may be a manifestation of conduction during partial recovery of myocardial excitability,[32] and the increased conduction delays of our patients with fibrillation could be a manifestation of abnormal cellular electrophysiology, as it may be found in diseased atrial muscle.[33] On the other hand, increased P-wave duration may be a reflection of atrial enlargement or disruption of the internodal and interatrial tracts,[34,35] or both.

Conduction of nonpremature stimuli did not differ in our patients with AF and the control subjects. Since these stimuli were applied at the right atrial appendage,

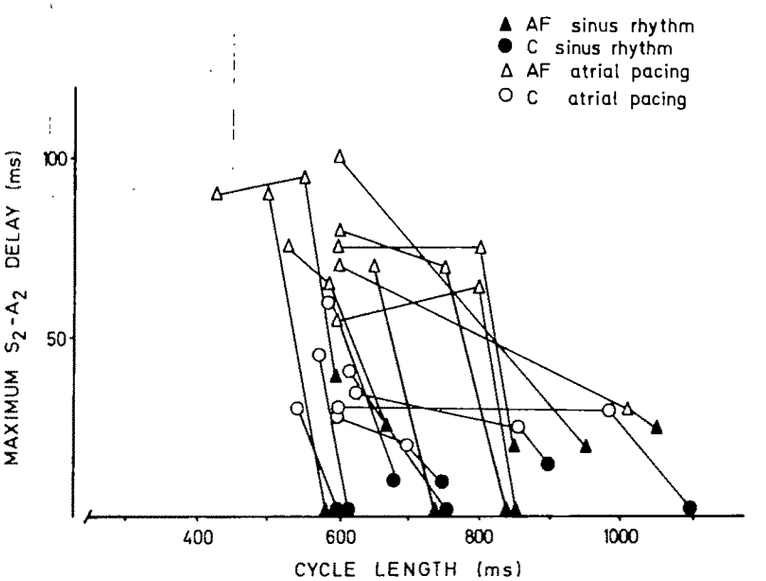

**FIGURE 5.** Graphic representation of the changes in maximal atrial conduction delay measured to any atrial site (maximal $S_2$-$A_2$ delay) produced by changes in cycle length by atrial pacing. Only the patients studied at least 1 cycle length close to the sinus cycle length are represented. The **solid lines** link the findings for the same patient at various cycle lengths. AF = atrial fibrillation group; C = control group. Values in milliseconds.

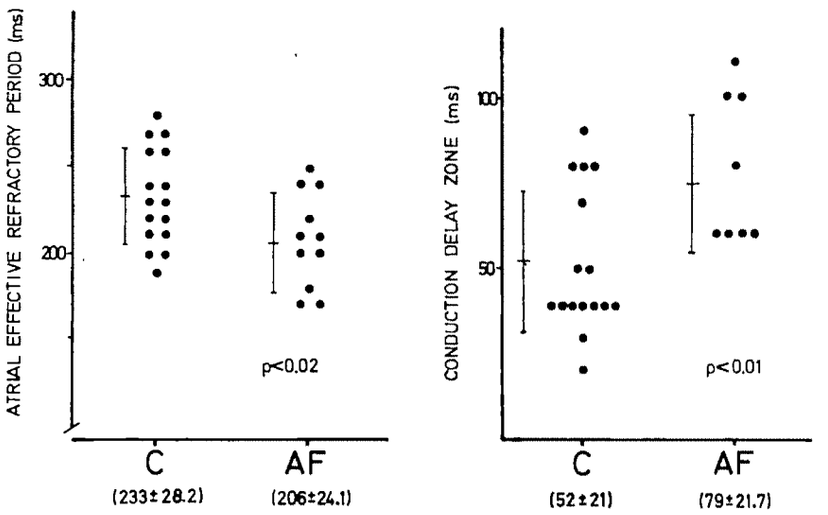

**FIGURE 6.** Graphic representation of atrial effective refractory periods and length of conduction delay zones in the atrial fibrillation (AF) and control (C) groups. Only the values for patients tested at paced basic cycle lengths between 500 and 650 ms are compared. The **vertical bars** represent the mean ± 1 standard deviation. Values in milliseconds.

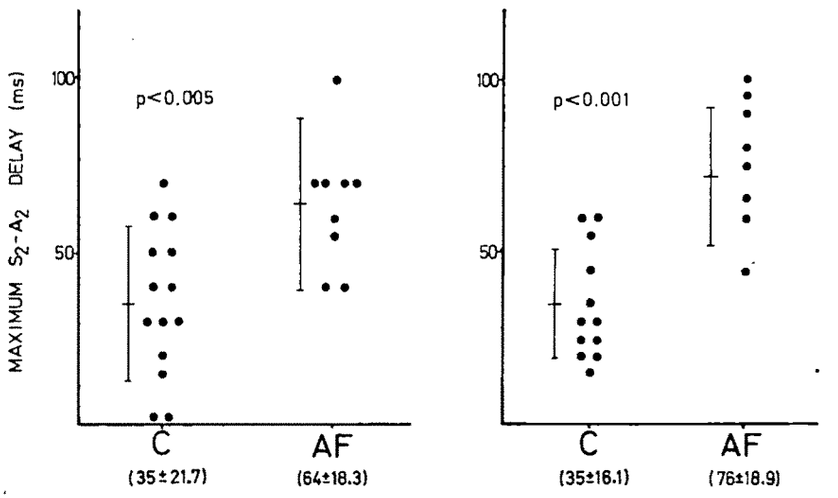

**FIGURE 7.** Graphic representation of the maximal conduction delays measured to the His bundle electrogram (**left**) and the coronary sinus (**right**) in the atrial fibrillation (AF) and control (C) groups. Only values during basic paced cycle lengths between 500 and 650 ms are shown. The **vertical bars** represent the mean ± 1 standard deviation.

AERP = atrial effective refractory period; AF = appearance of atrial fibrillation after 1 extrastimulus; CD = extrastimulus-induced atrial conduction delay; CDZ = conduction delay zone; CS = coronary sinus electrogram; HIS = His bundle electrogram; HRA = high right atrial electrogram; RR = atrial repetitive responses; SACT = sinoatrial conduction time (not corrected); SNRT = corrected sinus nodal recovery time; SP = secondary sinus pauses.

* Patients with supernormal conduction (see text for explanation).

Cycle lengths in boldface type represent sinus rhythm. <, >, ≥ indicate that the exact value could not be determined because of the appearance of atrial fibrillation. In the case of SNRT, it indicates that the pause was interrupted by pacing.

they were probably not conducted through the preferential atrial pathways; this may explain the apparent discrepancy with the prolongation of intraatrial conduction time found by others during sinus rhythm.[12,24]

The remarkable enhancement of atrial conduction delays by paced cycle lengths, without apparent close relation to rate, is an interesting phenomenon. Since both the stimuli pacing the basic rhythm and the extrastimulus were applied at the same point, the former ($S_1$) may have influenced the spread of the latter ($S_2$) by altering local activation sequences, perhaps promoting slow activation fronts,[32] that may increase local dispersion of recovery, and favor slow circuitous spread of $S_2$.[2,4,9,10] Studies of atrial conduction with extrastimuli applied to areas other than the one used to pace the basic rhythm may help clarify this point in the future.

Without intracellular recordings at the site of stimulation, it is difficult to rule out that the $S_2$-$A_2$ delays are caused by latency resulting from local tissue polarization by stimuli applied during the "absolute" refractory period.[36] However, several observations in our patients make this explanation very unlikely: (1) Latency would tend to produce equal delays to all sites, unless a change in excitation spread patterns also resulted. (2) Since latency depends mostly on stimulus intensity and duration,[36] similar delays should have been present in sinus and paced rhythms. (3) In case the $S_2$-$A_2$ delays were due to latency, the difference in the S-$A_2$ interval (during sinus rhythm) and the $S_2$-$A_2$ interval (during paced rhythm) at similar rates should be accompanied by a similar shortening of the effective atrial refractory period.[36] The pattern of $S_2$-$A_2$ delay in our patients did not fulfill any of these conditions.

The patients with AF also had a shorter atrial effective refractory period, and this should also favor reentry.[2] Similar findings were reported by Luck[20] in patients with atrial fibrillation and the sick sinus syndrome, but could not be confirmed by Bauernfeind[25] in patients with the Wolff-Parkinson-White syndrome. It is possible that different selected groups of patients may show variations in the electrophysiologic mechanisms underlying AF.

The incidence of repetitive atrial responses was similar in our patients with atrial flutter or fibrillation and the control subjects, indicating that this response is not a reliable index of a tendency to develop atrial arrhythmias spontaneously. Repetitive atrial responses have been used by some as an index of atrial vulnerability, this term often being used to imply a tendency towards atrial arrhythmias.[20,21] Our results coincide with other observations[22,23] in that atrial repetitive responses are a nonspecific finding. Animal studies show that the mechanism of these responses is local reentry around the point of stimulation, different in pattern from flutter or fibrillation circuits.[8–10] Notwithstanding, repetitive responses may create conditions favorable for the development of flutter or fibrillation[8–10]; this was the case in our experience and that of others.[11,12] We believe that the term atrial vulnerability should be used with caution in reference to the appearance of repetitive atrial responses. It is possible that the appearance of sustained flutter or fibrillation with a single extrastimulus may be a more specific sign of a tendency to spontaneously develop these arrhythmias[12]; however, no satisfactory conclusion appears possible with the information presently available.

The observations on supernormal conduction in 2 of the patients with AF merit some comment. Although supernormal intraatrial conduction may be a common phenomenon during premature stimulation,[37] it is conceivable that a combination of depressed conduction in some directions with enhanced conduction in others (as observed in some of our cases) may increase dispersion of the recovery of excitability, and facilitate arrhythmias of reentrant origin. A larger number of observations should be necessary to understand the role of supernormal conduction in atrial arrhythmogenesis.

The prevalence of clinically apparent or subclinical sinus nodal dysfunction was high in the patients with AF, but 50% of the patients had normal sinus function tests; sinus nodal dysfunction did not appear to be a necessary association for the development of fibrillation in the atria. The incidence of sinus nodal dysfunction in patients with AF will be markedly influenced by the patient selection protocol, and may be quite different among different series.

Some limitations of this study should be considered. Both the study and control groups included patients with a variety of clinical and electrophysiologic abnormalities, and this may have influenced the results in unpredictable ways. For this reason our results should be considered suggestive, and further studies in more homogeneous groups of patients appear necessary to better test their significance. Notwithstanding, certain observations were quite remarkable for such apparently mixed groups. For instance, the little superposition observed in the extrastimulus-induced conduction delays rarely reached 60 ms in the control group, while in most patients in the study group it surpassed that figure.

The rates at which our patients were tested were not completely uniform, due to the partly retrospective nature of the study. There was, however, no significant difference between the mean test cycle lengths in the AF cases (591 ± 32.2 ms) and in the control subjects (592 ± 32 ms; difference not significant). We preferred to include a larger number of observations, because our results suggested that it was mainly the fact that the basic cycle was paced, and not so much the pacing rate, which affected intraatrial conduction of the extrastimuli.

Not enough emphasis has been placed on the study of intraatrial conduction under premature stimulation in clinical electrophysiologic studies. Our observations suggest that intraatrial conduction of extrastimuli may be an important index of abnormal atrial electrophysiology, and a better knowledge of its changes in disease states may help us understand the pathogenesis of certain atrial arrhythmias.

**Acknowledgment:** This work would not have been possible without the dedication of Ines Alvarez, ATS, Begoña Elorriaga, ATS, Margarita Santos-Ascarza, ATS, Isabel Martin, AC, and Ana Morito, AC. Francisco Herrero gave us important technical assistance. We appreciate the cooperation of the Intensive Care Medicine Department (Chief, G. Schoendorff, MD).

# Problems in Health Data Analysis: The Maryland Permanent Pacemaker Experience In 1979 and 1980

LEONARD SCHERLIS, MD and DONALD H. DEMBO, MD

**In a recent report the Maryland statewide health data base, which is derived from "face sheet" data, was used to determine the appropriateness of permanent pacemaker insertion. In the present study the same indications were utilized and both the complete medical records and the face sheet were reviewed for those patients who had been classified as having permanent pacemakers inserted for inappropriate or questionable reasons. In 32 hospitals, 75% of the records were reviewed (610 of 817 patients). Although coded as having received permanent pacemakers, 16% had received temporary pacemakers, battery change, and the like. Diagnoses justifying permanent pacemaker insertion had been omitted in 53% of the face sheets, and coding errors were found in 39%. Although none of the 610 medical records reviewed had a valid indication for permanent pacemaker insertion listed on the face sheet, complete medical record review demonstrated valid indications in 95%. Inherent difficulties arise in attempting to list rigid indications for permanent pacemaker insertion. The face sheet does not provide adequate data for assessing the appropriateness of permanent pacemaker insertion.**

In Maryland, the availability of a computerized statewide health data system has afforded an opportunity for the analysis of many items present on the "face sheet" of the medical record. These include entries which by law are reported to the Maryland Health Services Cost Review Commission including day of admission, day of discharge, length of stay, discharge status, demographic data, date of birth, age, sex, coding of all diagnoses, coding of all procedures, and financial classification. In addition, the statewide data include financial information derived from billing data. Specific items excluded from the report to the statewide data system are the name of the patient and the name of the physician. The individual hospitals assign code numbers to both the patients and the physicians, and these data are only available to the hospital originating the information. The availability of such data provides excellent possibilities for the analysis and correlation of many important factors relating to health care delivery, including cost, quality measures, mortality, procedures, and hospital funding.

In a recent Health Research report,[1] *face sheet data* were utilized to determine whether permanent pacemakers had been inserted for appropriate reasons in Maryland during 1979 and 1980. After reviewing data from 2,222 permanent pacemaker insertions, it was concluded that 23% were unnecessary and an additional 13% were questionable. In the present study, both the complete medical records and the face sheet information were reviewed. The same indications for permanent pacemaker insertions were utilized in both studies in an effort to determine the validity of using only face sheet data for the determination of appropriateness of procedures. Additional consideration was given to the general problem of trying to establish guidelines for pacemaker insertion.

## Methods

With the cooperation of the Baltimore City Professional Standards Review Organization, the Maryland statewide data base for 1979 and 1980 was utilized to obtain the listing of all diagnoses for patients who had received permanent pacemakers during that time. The following procedure codes (ICD-9-CM)[2] were used:

From the Department of Medicine, Division of Cardiology, University of Maryland School of Medicine; and the Department of Medicine, Division of Cardiology, Maryland General Hospital, Baltimore, Maryand. Manuscript received November 22, 1982, accepted November 22, 1982.

Address for reprints: Leonard Scherlis, MD, Department of Medicine, Division of Cardiology, University of Maryland School of Medicine, 22 South Greene Street, Baltimore, Maryland 21201.

37.73 Insertion of permanent pacemaker into atrium, transvenous route

37.74 Insertion of permanent pacemaker into ventricle, transvenous route

37.75 Insertion of permanent cardiac pacemaker into unspecified site, transvenous route

37.76 Insertion of permanent pacemaker into epicardium
Implantation of electrode into myocardium by:
sternotomy
thoracotomy

37.77 Insertion of permanent cardiac pacemaker, unspecified approach
Implantation of permanent cardiac pacemaker, not otherwise specified

These procedures exclude the insertion of temporary pacemakers; replacement of battery, electrode, or pulse generators; mechanical complications; fitting and adjustment of cardiac pacemakers; and other codes relating to pacemakers. In addition, the diagnoses for patients identified by procedure code 37.70 (insertion of cardiac pacemaker not otherwise specified) were reviewed but not included in this report.

To compare this study with the Health Research report, which had been based only on face sheet information, we used the same indications as they did for permanent pacemaker insertions. These are listed as justifying implantation of a permanent pacemaker ("appropriate") (Table I), or as having ". . . proper indications under appropriate circumstances but which, by themselves, cannot be used as justifications for pacing" ("questionable") (Table II).

The participating Maryland hospitals were contacted and an explanatory letter sent to the head of cardiology. In addition, a release form was included and was to be signed by the Chief Executive Officer or his representative in each hospital. This form was addressed to the Information Service Center of the Staff of the Maryland Health Services Cost Review Commission, and authorized the release to the Quality Assurance Chairman of the requesting hospital the chart numbers of patients who had had permanent pacemakers implanted. The participating hospitals were then provided with a detailed computer printout for each of their patients whose record had been *coded* in the statewide data base as having received a permanent pacemaker, and for patients who had been *coded* as *not* having a diagnosis which justified the implantation of a permanent pacemaker—that is, both the unnecessary and questionable groups. These printouts are confidential data as they identify the patient by a medical record number.

In each hospital this printout was sent to the Quality Assurance Chairman and reviews of the medical record were undertaken, usually by members of the Quality Assurance committees. In several instances, members of the Utilization Review committees, teams of cardiologists, or heads of the

departments of medicine in their respective hospitals performed the reviews. A standard form was developed and provided for the detailed analysis of each medical record. Instructions were given for the diagnoses and codes to be copied from the face sheet, as were the procedures and their codes. The medical record review was then performed and additional diagnoses or procedures relating to pacemakers were listed. It was requested that the sources for these data be listed: consultation notes, operative notes, progress notes, electrocardiograms, and so on. In addition, the reviewer was asked (1) to indicate whether a permanent pacemaker was inserted; (2) to indicate whether a temporary pacemaker was inserted; (3) to indicate whether the pacemaker insertion was considered justified; and (4) to categorize any errors in charting utilizing a standard code for error types. A space for additional comments was provided.

The hospitals returned the completed forms and these were reviewed in detail. All codes for both diagnoses and procedures were verified, and all comments, information, and judgments on justification and classification of coding errors were reviewed. These were tabulated and provide the basis for this report.

## Results

The total number of permanent pacemakers implanted was found to be 2,182 for 1979 and 1980 in the present study, compared with the total of 2,222 in the Health Research report, a difference of <2%, employing the same indications. The number of pacemaker insertions in the unnecessary or questionable groups was 801 patients in our study, compared with 817 in the Health Research report, a difference of 2%. A total of 610 patient medical records (75% of the total of 817) have been reviewed in 32 of the 52 hospitals in Maryland, and these comprise the data for the present analysis. In 8 hospitals, there were either no insertions of new pacemakers or no record of any patient receiving a permanent pacemaker without having appropriate indications. Of the remaining 12 hospitals, 4 had only 1 to 3 inappropriate permanent pacemakers in 1979 and 1980 according to face sheet data. The remaining hospitals have not yet responded. In some hospitals included in this study, some charts were not available at the time of medical record review.

The Health Research report stated that all 801 patients included in their study had received permanent pacemakers. This statement was based on face sheet data recorded in the statewide data system. Detailed medical record analysis, however, showed that only 514 (84%) had actually had permanent pacemakers inserted. Thirteen (2%) of the patients previously classified as having had permanent pacemakers inserted had received replacement of battery units; 59 patients (10%) had received temporary pacemakers; and 24 patients (4%) were admitted with a *history* of a pacemaker having been inserted in the past but were not admitted for new pacemaker implants.

Recording problems were reviewed in detail, and 323 (53%) of the medical records reviewed revealed a significant omission on the face sheet in the recording of the appropriate diagnosis justifying the insertion of the pacemaker (Table III). Detailed medical record review in these patients demonstrated an appropriate diagnosis utilizing the same criteria as in the Health Research report (Table I). In 123 patient records (20%), the diagnosis listed on the face sheet was so vague that it was subject to misinterpretation by the coder. In 60 (10%) of the medical records, the diagnosis or operation was vague or unclear and was misinterpreted by the coder. Diagnoses were miscoded in the face sheets in 68 patients (11%) and procedures were miscoded in 81 patients (13%). Other coding or recording errors occurred 139 times (23%). Five examples are provided in Tables IV to VIII, which present diagnoses and procedures with

**TABLE IV Example A**

| | |
|---|---|
| I. Diagnosis—Face Sheet | |
| 1. Lymphoma—histocytic | 200.08 |
| 2. | 426.10* |
| II. Procedure—Face Sheet | |
| 1. Excision mass, left neck & right inguinal area | 86.3 |
| 2. Temporary transvenous pacemaker | 37.75* |
| 3. Permanent pacemaker | 37.72 |
| 4. Temporary transvenous pacemaker removed | 37.86 |
| III. Chart Review | |
| 1. Complete atrioventricular block | 426.0 |

* The only diagnosis listed on the face sheet was lymphoma. The coder assigned a code to the diagnosis and on review also assigned code 426.10. In ICD-9-CM, this code is atrioventricular block, unspecified. This diagnosis does not justify the implantation of a permanent pacemaker. However, complete atrioventricular block, 426.0, is a justifiable diagnosis. In addition, 37.75 is the code for a permanent pacemaker.

**TABLE V Example B**

| | |
|---|---|
| 1. Diagnosis—Face Sheet | |
| 1. Cardiac arrhythmia, treated | 427.9* |
| 2. Severe degenerative arthritis | 715.96 |
| 3. Osteoarthritis, right knee | 736.41 |
| 4. Genu valgus deformity | 733.00 |
| 5. Generalized osteoporosis | 997.4 |
| II. Procedures—Face Sheet | |
| 1. Temporary pacemaker | 37.74* |
| 2. Permanent pacemaker | 37.72 |
| III. Chart Review | |
| 1. Sick sinus syndrome | 427.81 |

* The coder assigned 427.9 to cardiac arrhythmia. In ICD-9-CM, this code is for cardiac dysrhthmia, unspecified. The specific diagnosis on chart review was sick sinus syndrome, 427.81, a justifiable diagnosis for permanent pacemaker insertion. In addition, 37.74 is the code for a permanent pacemaker.

**TABLE VI Example C**

| | |
|---|---|
| 1. Diagnosis—Face Sheet | |
| 1. Acute transmural myocardial infarction with pericarditis | 410.0 |
| 2. Cardiac failure secondary to ventricular tachycardia and ventricular fibrillation | 420.90 |
| 3. Secondary to digitalis (?) | 428.0 |
| 4. | 427.41 |
| 5. | 427.1 |
| 6. | 427.89 |
| II. Procedures—Face Sheet | |
| 1. Temporary pacemaker | 37.74* |
| III. Chart Review | |
| 1. No permanent pacemaker | |

* On chart review, this patient had a temporary pacemaker, not a permanent pacemaker. Code 37.74 is for a permanent pacemaker.

**TABLE VII Example D**

| | |
|---|---|
| I. Diagnosis—Face Sheet | |
| 1. Renal failure | 585 |
| 2. Hypertension | 401.9 |
| II. Procedures—Face Sheet | |
| 1. Temporary pacemaker | 37.72* |
| 2. Permanent pacemaker | 37.74 |
| III. Chart Review | |
| 1. Sinus arrest | 426.6 |
| 2. Sick sinus syndrome | 427.81 |

On chart review, diagnoses justifying the insertion of a permanent pacemaker were documented. In addition, 37.72 is the code for a permanent, not a temporary pacemaker.

**TABLE VIII Example E**

| | |
|---|---|
| 1. Diagnosis—Face Sheet | |
| 1. Aortic stenosis | 424.1 |
| II. Procedures—Face Sheet | |
| 1. Aortic valve replacement | 35.22 |
| 2. Insertion of permanent pacemaker | 37.75 |
| III. Chart Review | |
| 1. Complete heart block | 426.0 |

This patient had complete heart block after open heart surgery for aortic valve replacement. This required the insertion of a permanent pacemaker. Only aortic stenosis had been recorded and not complete heart block, 426.0.

the codes as copied from the face sheet of the medical records. On chart review, the additional diagnoses were listed and coded. Errors in diagnosis, coding, and in omission are documented.

After medical record analysis, 31 patients (5%) in the present study were found *not* to have the indications listed in the Health Research report which would justify the insertion of a permanent pacemaker (Table IX). If the same percentage were to apply to the total 817 patients in the "unnecessary or questionable category," this would represent a total of 42 patients or 2% of the total of 2,182 patients who received pacemakers in Maryland in 1979 and 1980, again utilizing the same criteria as in the Health Research report. However, among other indications, ventricular overdrive is a valid reason for pacemaker insertion and was not so listed in the Health Research report. Eight patients had a permanent pacemaker inserted in Maryland for this diagnosis. Inclusion of this group as justifiable reduces the unnecessary or questionable percentage to 4% of the 610 medical records reviewed. This would reduce the number which might be considered unnecessary or questionable to 1.4% of the total of 2,182 pacemakers inserted.

**TABLE IX The 31 Questionable or Unnecessary Pacemaker Implants* Encountered in Review of the Medical Records of 610 Patients**

| |
|---|
| 8 Ventricular overdrive |
| 3 Bifascicular block (1 acute myocardial infarction) |
| 1 Wenckebach, 1st and 2nd degree |
| 1 RBBB with second degree atriventricular block |
| 1 RBBB and atrial fibrillation with acute myocardial infarction |
| 1 RBBB with acute myocardial infarction |
| 1 LBBB with acute myocardial infarction |
| 1 LBBB and second degree atrioventricular block with acute myocardial infarction |
| 1 Mobitz I with acute myocardial infarction |
| 1 Mobitz I |
| 5 Unclear indications stated (2nd degree atrioventricular block; nonconducted premature atrial contractions) |
| 5 Not justified on chart review |
| 1 Postural hypotension and sinus bradycardia |
| 1 To permit use of beta blocking agent |

* Utilizing the same criteria as in the Health Research Report.

In a few instances, the hospital reviewers commented that the pacemaker insertion was judged appropriate although the criteria enumerated in the Health Research report were not present. The authors, however, included all of these cases as being inappropriate for the purpose of this report and in order to make a direct comparison of face sheet data with complete medical record review.

## Discussion

Although the event which precipitated this study was the release of the Health Research report, there have been serious concerns about conclusions based on data sources similar to those employed in that report. The flow of information from which these data were derived is generally as follows. When a patient is discharged from the hospital, the face sheet of the chart is filled out with the diagnoses and procedures and other information not relevant to this discussion. These entries may be made by the cardiologist or by the attending physician on a different service. These diagnoses and procedures frequently include only some of the important ones which characterize the hospitalization of the patient. The terms used to describe the disease of the patient are often only generally stated, and frequently emphasize the disease (for example, acute myocardial infarction) and less often the manifestations of the disease (chest pain, type of disturbance in rhythm, and so on). The patient record is then sent to the medical record department, where medical record technicians, clerks, or coding personnel assign codes as listed in ICD-9-CM to each diagnosis and procedure. In some hospitals, record personnel are specially trained to review the medical records in detail and to assign the codes for any additional diagnoses and procedures not listed on the face sheet. In other hospitals this function is not performed. These assigned codes are then transcribed to abstract forms, batched, and keyed into an external or internal data system. Regular reports are then provided to the participating hospital, and the data tapes are ultimately forwarded to the Maryland Health Services Cost Review Commission together with financial or billing data. These data are then made available for specific types of analyses once all confidential data have been removed. Thus, physician names or patient chart numbers are not generally available except to the individual hospital itself.

It is this statewide data system based on face sheet information that may be the basis for hospital funding, research, quality care studies, and other investigations. Several hospitals estimate that ≥15% of all patient records reaching the record department have no diagnosis or procedure listed at the time of patient dis-

charge. Record department personnel frequently assign code numbers after review of these medical records in the absence of a completed face sheet. Some hospitals assign a code number representing "undiagnosed disease, not specified as to site or system involved." These codes are then changed at a later date when final disease and operation data become available. Frequently, the patient records arrive in the medical record department before the operative notes or the discharge summaries have been completed. These data are therefore not available when the information on the face sheet is coded. In some hospitals, it was found that a copy of the face sheet is sent to the billing department immediately upon discharge, and codes are then assigned by billing personnel for insurance purposes. The record room department staff codes the face sheet attached to the medical record, resulting at times in different codes being assigned to the same patient. It is probable that there is a disparity between the statewide data coding and the coding provided by billing departments to insurance carriers.

Accreditation of hospitals by the Joint Commission on Accreditation of Hospitals requires that there be a Quality Assurance Committee and Program in each hospital.[3] These groups of physicians and allied health personnel maintain ongoing programs to assure quality care. Periodically, review of various medical problems are undertaken: that is, focused reviews. The local Professional Standards Review Organization, on review of the data from each hospital, may require hospital Utilization Review Committees or Quality Assurance Committees to perform selected focused review. The face sheet information is utilized on the basis of the following principle: "Face Sheet Discharge Data Are Only Indicators That Direct One To Review The Medical Record."

Physicians concentrate their documentation in the patient medical record. It is in the main body of the medical record that the admission history and physical examination, progress notes, record of treatment, plans for therapy, consultation notes, laboratory reports, nurses' notes, operative notes, and discharge summaries are found. The face sheet is *not* the focus of attention since the important details are in the body of the medical record and the face sheet is often a form to be quickly completed in order to sign the patient out of the hospital. Although the face sheet data may be utilized for the purpose of abstracting discharge data, for quality control, hospital funding, cost-effectiveness, and research, care should be exercised whenever such data are employed for these purposes. In some hospitals, the face sheet serves as the discharge summary. No final judgment can be made on medical diagnoses, procedures, or operations, severity of illness, mortality data, morbidity data, appropriate lengths of stay or other factors without a detailed review of the patient medical record.

The accuracy of the coding of the face sheet diagnoses and procedures is best when these are essentially simple and straightforward, and not subject to misinterpretation. They are more difficult when the diagnoses and procedures are complex, vague, and technical and when fine distinctions must be made between almost-identical terminology. Selected reviews by the Baltimore City Professional Standards Review Organization have revealed coding error rates of 5 to 24% for several hospitals in Baltimore City in the designation of a diagnosis to the wrong diagnostic related group. There is no standard "face sheet" in Maryland.

Physicians, with rare exception, are not familiar with the ICD-9-CM code system nor with its utilization in the medical record department for the statewide discharge data base. The physician may not use the appropriate nomenclature for diagnosis of the patient's disease, and may not use nomenclature precise enough to exclude erroneous ICD-9-CM codes from being assigned to the diagnoses listed. The physician may not include all of the manifestations of the disease. The coding may involve highly technical terminology, not familiar to the coding personnel or easily located in the code book.

Cardiac arrhythmias probably represent the one discipline of cardiology which is most technical in its terminology. In completing the face sheet, the physician may not mention the specific arrhythmia, or may state it vaguely or use an ambiguous term subject to misinterpretation. The coding personnel are then faced with making distinctions in this selection in order to assign a specific 4- or 5-digit code.

The present study was specifically directed at determining the relation between the codes as derived from the face sheet and the entire medical record contents themselves in an effort to determine whether the "justifying diagnosis" was clearly documented in the body of the medical record but not on the face sheet. The study participants in each hospital copied the face sheet diagnoses and procedures (including codes), and then reviewed the entire medical record for additional diagnoses or procedures. The hospitals which participated included university hospitals, teaching hospitals, and community hospitals from throughout the state and involved medical record department personnel, quality assurance personnel, utilization review staffs, cardiologists, and others. With few exceptions a distinct uniformity in the findings was observed in each hospital.

Specific problems encountered in review of the face sheet included the following, as determined from the medical record review: (1) omission of the diagnosis which justified the pacemaker insertion; (2) lack of specificity in listing the arrhythmia diagnosis; (3) coding problems due to nonspecific diagnosis being listed; (4) correct diagnosis listed but wrong code number assigned; (5) compound diagnosis for which the coder assigned a code to only part of the diagnosis and omitted the secondary codes; (6) failure of the physician to designate the type of pacemaker correctly; (7) pacemaker listed correctly but coded incorrectly; (8) sixth diagnosis that justified a pacemaker, but only 5 diagnoses entered into the available computer system.

As noted, 31 patients were not found to have the appropriate diagnosis for permanent pacemaker insertion according to the indications listed in the Health Research report. These indications were accepted only for the purpose of this study in order to permit a direct comparison of face sheet data with complete medical record review. More widely accepted indications, how-

ever, would further reduce the number of insertions listed as inappropriate in the present report. Permanent pacemakers were inserted in 8 patients for ventricular overdrive and their charts clearly justified these decisions. In 7 other patients, permanent pacemakers were inserted for bifascicular blocks or for the new onset of intraventricular conduction defects in the presence of acute myocardial infarction. These indications, as well as the insertion of a permanent pacemaker for postural hypotension with bradycardia, and to permit the use of beta blockers in the presence of bradycardia, are controversial but may be acceptable judgment decisions by the consulting physician.

Indications for cardiac pacemaking have been widely reported.[4–10] In general, pacing is appropriate for the control of symptomatic bradyarrhythmias, particularly bradyarrhythmias unresponsive to medical management. Pacemaker technology has expanded indications for permanent pacing. Synchronized (demand) capability, and physiologic (atrioventricular sequential) modes have extended pacer treatment to complex brady- and tachyarrhythmias. Even after 25 years of clinical use, however, we do not know in all cases just when to prescribe a permanent pacemaker.[11] Controversy is unresolved in new onset bundle branch block in the setting of ischemic heart disease,[8] in bifascicular and trifascicular block,[9] and in intermittent and undocumented symptomatic low cardiac output syndromes.[4]

Electrophysiologic testing with His bundle recordings and rapid pacing or drug-induced stress assessment of the conducting system is of proven value in some but not all uncertain pacemaker candidates. Often physiologic assessment is impractical. Moreover, the propriety of the practice in which only 1 or 2 pacemakers per year is inserted in some hospitals is unresolved. In 1 report, retrospective peer review was apparently successful in reducing the number of permanent pacemaker insertions.[12] Peer review as generally practiced in many Maryland hospitals offers the best assurance for appropriate utilization.

**Acknowledgment:** This study was carried out under the aegis of the Maryland Society of Cardiology Ad Hoc Committee on Permanent Pacemakers (Stephen C. Achuff, MD, Dean R. Taylor, MD, Donald H. Dembo, MD, and Leonard Scherlis, MD, Chairman). The Baltimore City Professional Standards Review Organization was instrumental in making this study possible. Appreciation is extended to each of the 32 hospitals whose medical staff, medical record department personnel, and review groups performed all of the detailed medical record reviews. Particular appreciation is extended to Suzanne Murphy for her advice. We also thank Shirley Heath, who helped coordinate this study and prepare the final report.

# NOW IT'S HERE... ONCE-A-DAY 24-HOUR ANGINA PROPHYLAXIS

# TRANSDERM®-NITRO

nitroglycerin

# once-a-day

# Transderm®-Nitro

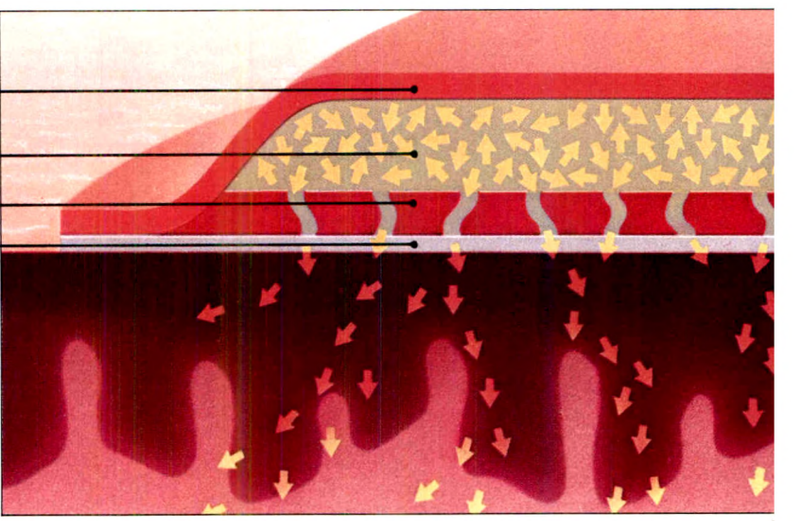
## nitroglycerin

### Exclusive rate-controlling membrane delivers hour-by-hour precision dosage

- Specially designed copolymer membrane governs, and limits, rate at which drug diffuses from the system to the skin.
- Similar to an intravenous *infusion*, Transderm-Nitro delivers medication at a constant rate.
- Patients are protected against extremely high concentrations being reached even where skin is unusually permeable.

(actual size)

(approx. thinness)



### Magnified cross section of Transderm-Nitro system

**impermeable water-resistant backing layer**

**nitroglycerin reservoir**

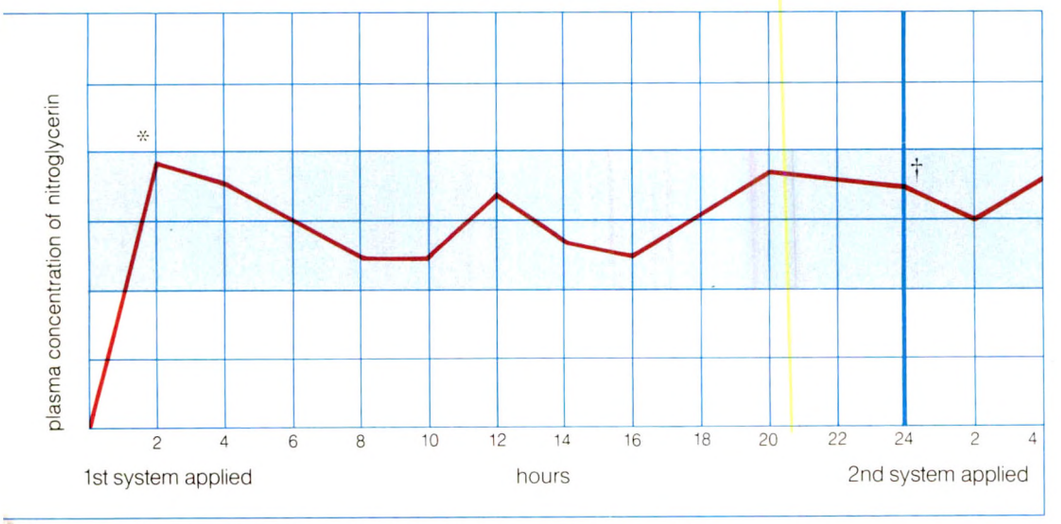
**rate-controlling membrane**

**hypoallergenic contact adhesive**
Contains an initial dose of medication to saturate skin-binding sites so that absorption begins immediately

# Precision dosage system assures 24-hour angina protection

### Steady, sustained 24-hour nitroglycerin levels

Constant protection against angina attacks assured by uninterrupted plasma concentrations of nitroglycerin: Transderm-Nitro 5 rated to release 5 mg/24 hours; Transderm-Nitro 10 rated to release 10 mg/24 hours.



Orthostatic hypotension may indicate nitroglycerin overdosage; reduce dosage if symptoms occur. Nitrates are contraindicated in patients with increased intraocular pressure. Withdrawal should be gradual if treatment is terminated. Do not apply to distal parts of the arms and legs.

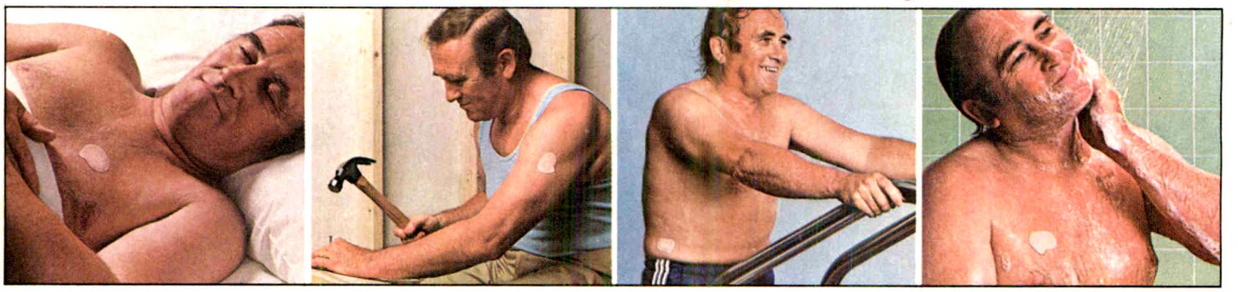
### System is simple and easy to use

- Every 24 hours the old system is removed and the new one applied.
- Therapeutic effect can be anticipated 30 minutes after application and maintained for 30 minutes following removal.
- Can be applied anywhere on the body except the distal extremities.

### An advance beyond tablets and ointments

- 24-hour sustained therapeutic blood levels of nitroglycerin
- Precise dosage control
- Ease of administration...avoids mess and inconvenience of ointments
- Once-a-day dosage to enhance compliance
- May be worn while swimming, bathing and showering

*First measurement in this study was taken at 2 hours. However, a therapeutic effect can be anticipated 30 minutes after application of the system, and will be maintained for 30 minutes after its removal.



†After 24 hours, system is removed and a new one is applied to another site. Renewal of the system does not result in any significant alteration in the plasma levels, as long as the change is made without delay.

CIBA

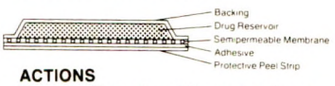
# Transderm®-Nitro nitroglycerin

## Once-a-day, 24-hour protection against angina attacks

System can be applied anywhere except distal extremities. Doesn't compromise daily activities.

**Transderm®-Nitro**
(nitroglycerin)
**Transdermal Therapeutic System**



### DESCRIPTION

Transderm-Nitro (nitroglycerin) transdermal therapeutic system is a flat unit designed to provide controlled release of nitroglycerin through a semipermeable membrane continuously for 24 hours following application to intact skin. Nitroglycerin (glyceryl trinitrate) is a prompt-acting vasodilator for the relief and prevention of anginal attacks. Systems are rated to release *in vivo* 5 and 10 mg nitroglycerin over 24 hours and are in sizes of 10 and 20 $cm^2$ respectively.

One-fifth of the total nitroglycerin in the system is delivered transdermally to the patient over 24 hours; the remainder serves as the thermodynamic energy source to release the drug and remains in the system. The rated release of drug is dependent upon the area of the system; 0.5 mg nitroglycerin is delivered *in vivo* for every $cm^2$ of system size.

The Transderm-Nitro system comprises four layers as shown below. Proceeding from the visible surface toward the surface attached to the skin, these layers are: 1) a tan-colored backing layer (aluminized plastic) that is impermeable to nitroglycerin; 2) a drug reservoir containing nitroglycerin adsorbed on lactose, colloidal silicon dioxide, and silicone medical fluid; 3) an ethylene/vinyl acetate copolymer membrane that is permeable to nitroglycerin; and 4) a layer of hypoallergenic silicone adhesive. Prior to use, a protective peel strip is removed from the adhesive surface.

Cross section of the system:

### ACTIONS

When the Transderm-Nitro system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before being inactivated by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilatation and pooling. The major beneficial effect of nitrogiycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation and consequent reduced cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In clinical studies transdermal absorption of nitroglycerin from a nitroglycerin system occurred in a continuous and well-controlled manner, for a minimum of 24 hours. Therapeutic effect can be anticipated 30 minutes after application of the system and to be maintained for 30 minutes after its removal.

### INDICATIONS AND USAGE

Transderm-Nitro system is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

### CONTRAINDICATIONS

Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

### WARNINGS

In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

### PRECAUTIONS

Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

### ADVERSE REACTIONS

Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

### DOSAGE AND ADMINISTRATION

Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.

The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response.

The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension, especially during orthostasis, indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.

Do not store above 86°F (30°C).

### PATIENT INSTRUCTIONS FOR APPLICATIONS

A patient leaflet is supplied with the systems.

# Cellular Electrophysiologic Abnormalities of Diseased Human Ventricular Myocardium

ROBERT F. GILMOUR, Jr., PhD, JAMES J. HEGER, MD, ERIC N. PRYSTOWSKY, MD, and DOUGLAS P. ZIPES, MD

**Using standard microelectrode techniques, the cellular electrophysiologic features of ventricular myocardium resected from 8 patients with refractory arrhythmias were studied in vitro. Action potentials from damaged myocardium compared with normal myocardium had reduced resting membrane potential, amplitude, and maximal upstroke velocity. Tetrodotoxin, but not verapamil, suppressed 3 action potentials with resting potentials of −60 to −64 mV and $V_{max}$ <70 V/s. Verapamil, but not tetrodotoxin, suppressed 4 action potentials with resting potentials of −44 to −57 mV and $V_{max}$ <20 V/s. Unidirectional block, Wenckebach block, and summation occurred in damaged zones. Exit block from and frequency-dependent entrance block into an ectopic focus were noted. Subthreshold responses in the focal area induced by action potentials in the surrounding myocardium and by subthreshold current pulses injected through the recording microelectrode altered the spontaneous discharge rate of the focus, as previously described for modulated parasystole. Pulses early in the spontaneous cycle delayed the next expected discharge, and later pulses accelerated the subsequent discharge. Pulses injected at the singular point completely suppressed automaticity (annihilation). Tetrodotoxin and verapamil suppressed automaticity in some fibers. Single action potentials induced in quiescent fibers triggered and terminated sustained rhythmic activity. These data suggest that depressed fast responses, slow responses, and subthreshold potentials can generate and modulate ectopic activity in damaged human ventricle and that fast- and slow-channel blocking agents and single premature stimuli can terminate such activity.**

Diverse cellular electrophysiologic phenomena have been found in resected human ventricular tissue studied in vitro.[1–5] Some of these phenomena such as slow conduction, decreased excitability, and various forms of abnormal automaticity may contribute to the development of arrhythmias in diseased human ventricles. However, few studies of human ventricular preparations have been reported, and it is likely that many abnormal cellular electrical properties of these tissues have not been identified. For example, slow-channel blocking agents, but not tetrodotoxin, depress the action potential upstroke of depolarized human ventricular cells.[1,2,5] These observations differ from those in studies of ischemic or hypoxic canine[6–8] and hamster[9] myocardium, in which lidocaine and tetrodotoxin suppressed abnormal action potentials but verapamil and D600, its methoxy derivative, did not. In view of these conflicting findings, further studies of depressed fast responses and slow responses in human ventricle appear warranted. In addition, aspects of modulated pacemaker activity as suggested by experiments in normal cardiac tissues subjected to abnormal environments[10–13] have not been examined in diseased human ventricle. These phenomena include phase resetting and annihilation by subthreshold and regenerative action potentials and modulation of reflected and parasystolic excitation patterns. Low-amplitude potentials that reach threshold may also trigger sustained rhythmic activity,[14–16] an event that has not been fully investigated in the human ventricle.[3,4]

Krannert Fund; by Grants HL-06308, HL-07182, and HL-18795 and by the Young Investigator Award HL-24851 from the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland; and by the American Heart Association, Indiana Affiliate Inc., Indianapolis, Indiana. Manuscript received January 29, 1982; revised manuscript received June 1, 1982, accepted June 16, 1982.

Address for reprints: Robert F. Gilmour, Jr., PhD, Indiana University School of Medicine, Krannert Institute of Cardiology, 1100 West Michigan Street, Indianapolis, Indiana 46223.

Because cardiac arrhythmias may be due to disorders of impulse formation, impulse propagation, or a combination of both mechanisms, we investigated aspects of abnormal automaticity and conduction in resected human ventricle that have not previously been examined in detail. The purpose of these studies was to test the hypotheses that (1) both slow responses and depressed fast responses exist in diseased human ventricle and can participate in abnormal conduction and pacemaker activity; (2) subthreshold potentials can also contribute to abnormal automaticity and conduction, as predicted by experimental models of oscillatory activity[10,17] and Wenckebach periodicity[18,19]; and (3) subthreshold afterdepolarizations may reach threshold after an appropriate stimulus and trigger sustained rhythmic activity.

## Methods

Seventeen ventricular preparations obtained from 8 patients, 7 men and 1 woman aged 52 to 73 years (Table I), were studied. Seven patients had ischemic heart disease associated with various degrees of heart failure, whereas 1 patient had no evidence of organic heart disease and was characterized as having primary electrical disease. All patients had recurrent ventricular tachycardia resistant to treatment with multiple standard and investigational antiarrhythmic agents. Left ventricular aneurysmectomy and endocardial resection was performed in the 7 patients with ischemic heart disease, and right ventricular myocardial resection was performed in the 1 patient with primary electrical disease. Areas were selected for resection on the basis of the site of earliest myocardial activation during ventricular tachycardia initiated at operation by programmed electrical stimulation. Myocardial activation sequences were determined using epicardial and endocardial mapping with a ring electrode and reference electrodes sewn to the right and left ventricular epicardium.[20]

The patient with primary electrical disease continued to have recurrent ventricular tachycardia after surgery, whereas 6 of the 7 other patients had no episodes of symptomatic or sustained ventricular tachycardia during follow-up periods of 5 to 38 months (Table I). One patient did not have ventricular tachycardia after surgery, but died 6 days postoperatively because of the low cardiac output syndrome. Cardiac glycosides were discontinued 1 day before surgery in all patients. Antiarrhythmic agents were discontinued 1 to 7 days before surgery in 6 patients. One patient (Patient 5) received amiodarone the day before surgery and was assumed to have therapeutic levels of the drug at operation. Patient 7 was administered procainamide at surgery to facilitate the induction of ventricular tachycardia. All patients were anesthetized with morphine and nitrous oxide during surgery.

At surgery the pieces of resected myocardium were placed immediately in Tyrode's solution (22° to 24°C) previously bubbled with 95% oxygen and 5% carbon dioxide and taken from the operating room to the cellular electrophysiology laboratory. The composition of the Tyrode's solution (m*M*) was: $MgCl_2$, 0.5; $NaH_2PO_4$, 0.9; $CaCl_2$, 2.7; NaCl, 137.0; $NaHCO_3$, 12.0; KCl, 4.0; glucose, 5.0. The pieces were then transferred to a tissue bath and superfused at a rate of 5 ml/min with oxygenated Tyrode's solution maintained at 37° ± 0.5°C, pH 7.35 ± 0.05, and $pO_2$ >400 mm Hg.

The preparations were allowed to beat spontaneously or were driven at a basic cycle length of 1,000 ms in the tissue bath for at least 30 minutes before study. Stimuli were rectangular pulses 2 ms in duration and an intensity twice diastolic threshold delivered through bipolar Teflon®-coated stainless steel electrodes. Transmembrane potentials were recorded with glass microelectrodes filled with 3 *M* KCl (DC resistance, 5 to 30 mΩ) coupled to silver-silver chloride wires leading to high impedance, capacitance-neutralizing amplifiers (model 701 or 707, W-P Instruments). The amplifiers were equipped with rapid switching systems that permitted the delivery of depolarizing and hyperpolarizing current pulses through the recording microelectrode. After delivery of the pulse, the amplifier reverted to the recording mode and the resulting voltage deflection was monitored. Electronic differentiation was used to obtain the first time derivative of the action potential upstroke. The recordings were displayed on a memory oscilloscope (Tektronix D15), photographed with a Polaroid® camera (C-59), and recorded on magnetic tape (Hewlett-Packard model 3960).

Recordings were obtained from abnormal and normal cells on the endocardial surface in 5 preparations and from the mid-myocardial surface in the remaining 8. Typical dimensions of the preparations were 5 cm long × 2.5 cm wide × 5 mm thick. The terms *abnormal* and *normal* are based on cellular electrophysiologic characteristics only. Cells were considered normal when their action potential characteristics fell within the range of values previously reported for presumably normal human ventricle.[1,3] Cells having action potential characteristics that fell outside this range were considered abnormal. However, the data reported in previous studies were obtained

**TABLE I Clinical Data on the 8 Patients Studied**

| Patient | Age (yr) & Sex | Diagnosis | Medications* | Area Resected | Follow-Up |
|---|---|---|---|---|---|
| 1 | 56M | PED | Aprindine | RV free wall, endo | VT, encainide (43 mo) |
| 2 | 52M | IHD | Digoxin, aprindine | LV endo of anterior wall at junction with septum | No VT, quinidine (38 mo) |
| 3 | 71M | IHD | Encainide, amiodarone, digoxin | LV endo at distal septum at junction with free wall | No VT (15 mo) |
| 4 | 62M | IHD | Digoxin, mexiletine, amiodarone, encainide | Widespread LV endo resection | No VT (11 mo) |
| 5 | 73M | IHD | Digoxin, quinidine, amiodarone† | Widespread LV endo resection | Died 6 days po due to LV failure; no VT |
| 6 | 70F | IHD RVD | Digoxin, quinidine | Large LV endo scar | No VT (7 mo) |
| 7 | 68M | IHD | Quinidine, digoxin, procainamide‡ | Large LV endo scar | No VT (8 mo) |
| 8 | 50M | IHD | Digoxin, lidocaine | LV endo near apex | No VT (5 mo) |

* Cardioactive drugs given 1 to 7 days before surgery. † Discontinued 1 day before surgery. ‡ Given at surgery.
Endo = endocardium; IHD = ischemic heart disease; LV = left ventricular; PED = primary electrical disease; po = postoperatively; RV = right ventricular; RVD = rheumatic valvular disease; VT = ventricular tachycardia.

from human hearts with some form of myocardial disease. Furthermore, because of similar action potential characteristics of human ventricular muscle and Purkinje tissue, we were unable to determine whether normal action potentials represented healthy ventricular muscle cells or slightly depressed Purkinje cells. Normal action potentials in this study were recorded from cells surrounding the aneurysm or necrotic areas or from islands of normal myocardium interspersed with areas of focal necrosis. Areas of the preparations that appeared to have been crushed during resection were excised and no data were collected from areas of myocardium near the cut edges of the specimens.

To determine whether the fast or the slow inward current mediated the upstrokes of abnormal cells, 7 cells with resting membrane potentials <−65 mV and maximal upstroke velocities <70 V/s were superfused first with Tyrode's solution containing tetrodotoxin ($5 \times 10^{-6}$ *M*) for 15 minutes followed by 30 minutes of washout and then with racemic verapamil ($2 \times 10^{-6}$ *M*) for 30 minutes. Verapamil was not given first to any of the preparations because its effects are not completely reversible in vitro.[21] Statistical analysis was performed using Student's *t* test for unpaired data.

## Results

**Action potential characteristics:** The action potential characteristics of abnormal ventricular myocardium were compared with those of apparently normal myocardium (Table II). Action potentials from abnormal cells usually had reduced resting membrane potential, action potential amplitude and duration, and maximal upstroke velocity of phase zero. However, in 2 cells from Patient 5 and 2 cells from Patient 6, variable amplitude action potentials were elicited from resting membrane potentials of −70 to −79 mV. The amplitudes and upstroke velocities of these action potentials depended on stimulus intensity, frequency, and polarity. In the example shown in Figure 1, bipolar cathodal stimulation consistently produced action potentials with amplitudes of approximately 91 mV (superimposed action potentials labelled 1 and 2). Anodal pulses elicited lower amplitude action potentials whose upstrokes were increasingly delayed in onset and reduced in amplitude (action potentials 3 to 11), until only a subthreshold depolarization was produced (labelled 12). The next stimulus after the subthreshold depolarization produced an action potential with a relatively large amplitude (action potential 13) and the sequence of progressive action potential depression was repeated (not shown). Data for the variable amplitude action potentials were not included in Table II.

**TABLE II Action Potential Characteristics**

| | RP (mV) | APA (mV) | APD50 (ms) | APD90 (ms) | $\dot{V}_{max}$ (V/s) |
|---|---|---|---|---|---|
| Normal | −81.0 | 109.7 | 249.3 | 378.3 | 219.0 |
| (n = 10) | ±1.2 | ±1.4 | ±15.2 | ±23.4 | ±23.5 |
| Abnormal | −60.8* | 75.5* | 112.2* | 206.3* | 45.8* |
| (n = 14) | ±1.7 | ±3.0 | ±15.9 | ±27.6 | ±9.1 |

* Statistically significantly different from normal to $p < 0.05$. Data are given as mean ± standard error of the mean.

APA = action potential amplitude; APD50 = action potential duration at 50% of repolarization; APD90 = action potential duration at 90% of repolarization; RP = resting potential; $\dot{V}_{max}$ = maximal action potential upstroke velocity.

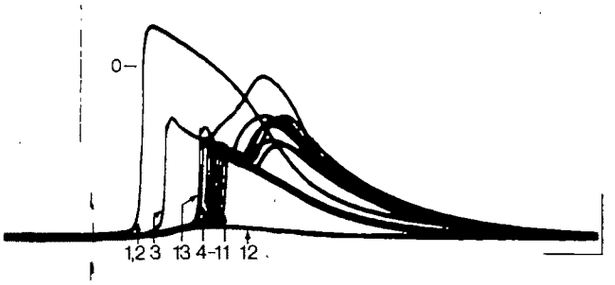

**FIGURE 1.** Consecutive superimposed recordings of variable amplitude action potentials in a human ventricular cell during stimulation at a basic cycle length of 1,000 ms. Action potentials and subthreshold responses are numbered sequentially in the order in which they occurred. Stimulus duration and intensity were constant at 2 ms and 100 V, respectively. The maximal diastolic potential was −75 mV. Vertical calibration, 25 mV. Horizontal calibration, 50 ms. Data obtained from Patient 6. See text for discussion.

**Conduction disturbances:** *Stimulus-dependent block:* Abnormal action potentials, as characterized in Table II, were associated with slow conduction and variable degrees of conduction block. Conduction across some areas of abnormal myocardium was facilitated by increasing the stimulus intensity, duration, or cycle length. An example of the dependence of conduction on stimulus frequency is shown in Figure 2. In this preparation microelectrode recordings were obtained from cells on opposite sides of an area of depressed conduction. One-to-one conduction across the depressed segment occurred at basic cycle lengths >1,100 ms (not shown), but 2:1 and higher degrees of block developed

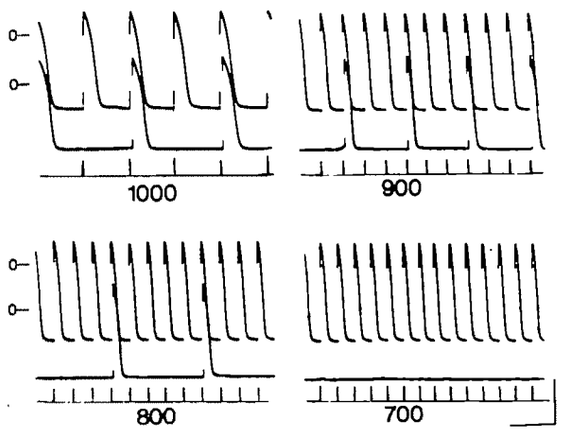

**FIGURE 2.** Increased degree of conduction block in diseased human ventricle with increasing stimulus frequency. Two microelectrode recordings were obtained from relatively normal cells on opposite sides of an area of abnormal cells approximately 14 mm wide. A bipolar stimulating electrode was placed in 1 of the normal areas. In each panel the upper action potentials were recorded near the stimulating electrode and the lower action potentials were recorded on the opposite side of the abnormal area. The bottom recording is the stimulus interval, which is given in milliseconds below each panel. The stimulus polarity, duration, and intensity were constant throughout at cathodal, 2 ms, and 10 V, respectively. Vertical calibration, 50 mV. Horizontal calibration, 1 second for a stimulus interval of 1,000 ms and 2 seconds for the rest. Data obtained from Patient 1. See text for discussion.

as the basic cycle length was shortened from 1,000 to 800 ms. Complete block occurred at a basic cycle length of 700 ms.

A similar relation between stimulus frequency and conduction was seen in another preparation (Fig. 3). However, in this preparation, 1:1 conduction across an area of abnormal cells occurred at shorter cycle lengths when the stimulating site was on one side of the abnormal area (X2) rather than the other (X1). As plotted in Figure 3, stimulation at site X1 during control produced 1:1 responses at the recording site near the stimulating electrode (the proximal site) and at a recording site on the opposite side of the preparation (the distal site) at a cycle length of 1,300 ms. Thus, the ratio of the distal response (DR) to the proximal response (PR) was 1.0. Two-to-one block developed at a cycle length of 1,200 ms, producing a DR/PR ratio of 0.5, and complete block occurred at a cycle length of 400 ms. One-to-one conduction occurred at a cycle length of 1,000 ms during control stimulation of site X2, with complete block at the distal recording site at a cycle length of 700 ms.

After control measurements, the preparation was exposed to isoproterenol ($10^{-7}$ *M*) for 10 minutes in an attempt to facilitate conduction.[22] After isoproterenol the cycle length at which 1:1 conduction occurred during pacing at site X1 shortened from 1,300 to 600 ms and complete block was not produced even at a cycle length of 400 ms (the proximal site did not respond 1:1 when the cycle length was shortened further). The cycle lengths at which 1:1 conduction and complete block were produced during stimulation at site X2 also were reduced after isoproterenol exposure, but to a lesser extent. Thus, isoproterenol effectively reversed the direction of block at some pacing cycle lengths.

*Summation:* The site of stimulation also could affect the configuration of action potentials in abnormal cells. In the preparation shown in Figure 4, stimulation of a relatively normal area of myocardium (X1) or an abnormal area (X2) produced a normal action potential near X1 and a slowly rising action potential ($V_{max}$ <10 V/s) near X2. Simultaneous stimulation of X1 and X2 also produced a normal action potential near X1, but markedly altered the action potential near X2. The maximal upstroke velocity of the abnormal cell was increased to approximately 40 V/s and there was less delay between the onset of the stimulus and the maximal action potential amplitude.

**Entrance and exit block:** In 2 preparations, a spontaneously discharging ectopic focus could be captured by action potentials elicited in the surrounding myocardium (Figs. 5 and 6). Stimulating the area surrounding 1 focus at a cycle length >1,200 ms resulted in 1:1 capture of the ectopic area with some delay (Fig. 5A). However, conduction into the focus from the stimulus site was unidirectional, because spontaneous action potentials generated by the focus did not produce an active response in the surrounding myocardium (Fig. 5B). Shortening the pacing cycle length from 1,200 to 400 ms produced increasing degrees of entrance block into the ectopic focus, and the coupling interval changed from 1:1 to 4:3, 3:2, 2:1, 3:1, and 4:1 (Fig. 6). At cycle lengths of 1,100, 1,000, and 800 ms, activation of the ectopic area showed Wenckebach-like characteristics, that is, activation times increased progressively before

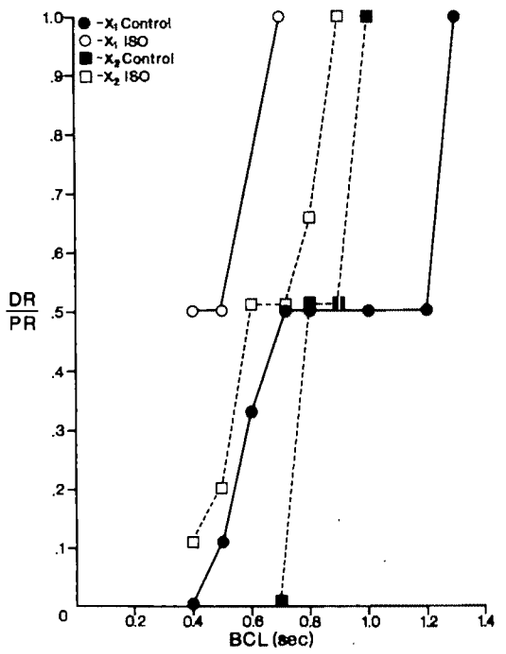

**FIGURE 3.** Dependence of conduction on pacing site and frequency in diseased human ventricle before and after exposure to isoproterenol (ISO) ($10^{-7}$ *M* for 10 minutes). Bipolar stimulating electrodes and recording microelectrodes were placed in relatively normal myocardium on opposite sides of an area of abnormal myocardium approximately 10 mm wide. Site X1 (**circles**) or site X2 (**squares**) was stimulated during control (**black symbols**) and after exposure to ISO (**white symbols**). Responses at the microelectrode site near the respective stimulating electrode (the proximal response [PR]) and on the opposite side of the depressed area (the distal response [DR]) were monitored. The ratio DR/PR is displayed as a function of the pacing basic cycle length (BCL) in milliseconds. Stimulus polarity, duration, and intensity were constant throughout at cathodal, 2 ms, and 20 V, respectively. Data obtained from Patient 1. See text for discussion.

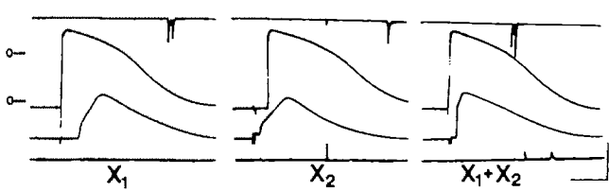

**FIGURE 4.** Summation in diseased human ventricle. Bipolar stimulating electrodes and recording microelectrodes were placed at a site along the border between an area of abnormal myocardium and relatively normal myocardium (X1) and at a site within the abnormal area (X2). The recordings shown are, **from top to bottom**, upstroke velocity of the border zone cell, action potential of the border zone cell, action potential of the abnormal zone cell, and upstroke velocity of the abnormal zone cell. Cycle length = 1,000 ms and stimulus intensity = 100 V. Stimulus duration = 3 ms for X1 and 6 ms for X2. Vertical calibration, 200 V/s for the top and bottom recordings and 50 mV for the middle recordings. Horizontal calibration, 10 ms for the top and bottom recordings and 100 ms for the middle recordings. Data obtained from Patient 3. See text for discussion.

block and activation times after the blocked action potential were relatively short. However, at cycle lengths of 900, 600, and 400 ms, the interval between complexes in the normal zone and in the ectopic zone were constant before and after block.

**Depressed fast responses and slow responses:** Tetrodotoxin had little effect on the action potentials of 4 cells with resting membrane potentials ranging from −44 to −57 mV and maximal upstroke velocities <20 V/s. In these cells, verapamil markedly reduced the amplitude and rate of rise of the action potential upstroke. An example of the effects of tetrodotoxin and verapamil on action potentials in a relatively normal cell and an abnormal cell is shown in Figure 7, A and B. Tetrodotoxin produced activation delay and intermittent conduction block in the normal zone but had little effect on the action potential of the abnormal cell. Verapamil reduced the action potential amplitude of the abnormal cell without affecting its resting membrane potential and slightly reduced action potential amplitude and maximal upstroke velocity in the normal cell. In 3 other cells with resting membrane potentials of −60 to −64 mV and maximal upstroke velocities <70 V/s, tetrodotoxin markedly reduced action potential amplitude and maximal upstroke velocity (Fig. 7C), whereas verapamil only slightly reduced action potential amplitude (not shown).

**Automaticity:** *Triggered activity:* Six of the resected pieces were discharging spontaneously at the time of study. Maximal diastolic potentials of automatic cells ranged from −72 to −33 mV, and spontaneous activity arose from early and delayed afterdepolarizations and from gradual diastolic depolarization. Sustained rhythmic activity could be triggered by single stimulated action potentials or by short trains of stimulation in 2 preparations. An example of the latter phenomenon is shown in Figure 8A. In this preparation, recordings were obtained from 8 sites along a single trabeculum approximately 11 mm long that separated 2 areas of infarcted myocardium. At 1 recording site near the

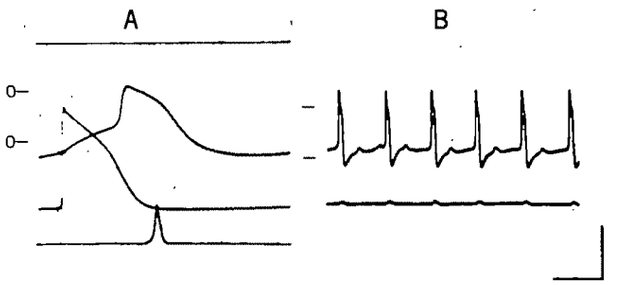

**FIGURE 5.** Exit block from an ectopic focus in diseased human ventricle. **Panel A,** action potential and upstroke velocity recordings from a cell in an abnormal area of myocardium (**upper recordings**) and a cell in relatively normal surrounding myocardium (**lower recordings**) during pacing of the normal myocardium at a cycle length of 1,200 ms. **Panel B,** recordings of the same 2 cells in the absence of pacing. Vertical calibration, 50 mV and 200 V/s. Horizontal calibration, 100 ms in left panel and 4 seconds in right panel. Data obtained from Patient 4. See text for discussion.

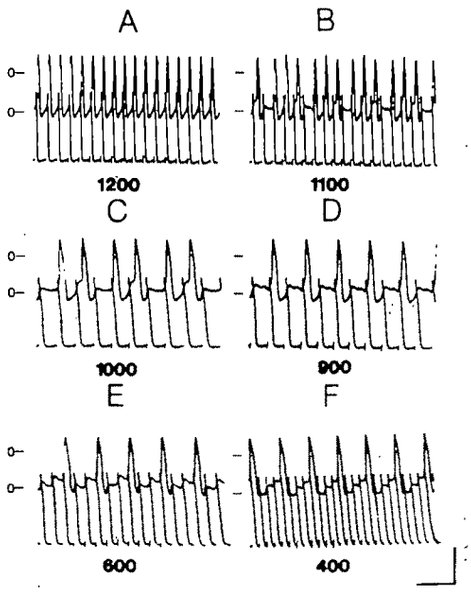

**FIGURE 6.** Frequency-dependent entrance block into an ectopic focus. Same preparation and recording sites as in Figure 5. In **panels A to F** the normal myocardium surrounding the focus was stimulated at progressively shorter cycle lengths, indicated beneath each panel in milliseconds. Vertical calibration, 50 mV. Horizontal calibration, 4 seconds in **A and B** and 2 seconds in **C to F.** See text for discussion.

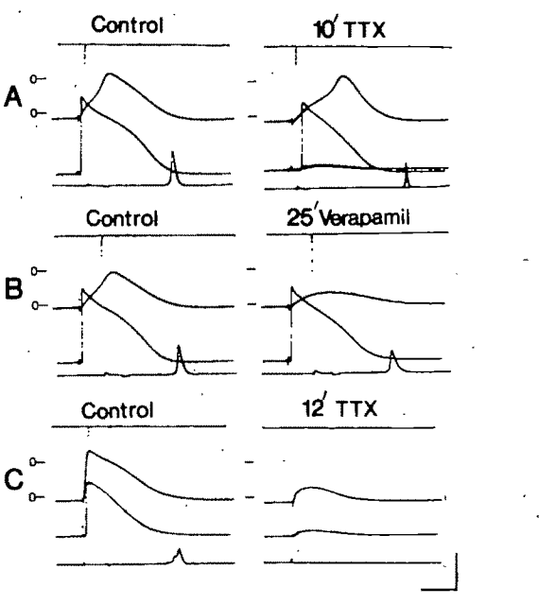

**FIGURE 7.** Effects of tetrodotoxin (TTX) and verapamil on action potentials in diseased human ventricle. **Panel A,** action potential and upstroke velocity recordings from an abnormal cell (**upper recordings**) and a relatively normal cell (**lower recordings**) before and after exposure to TTX for 10 minutes. **Panel B,** after washout of TTX the same 2 cells were exposed to verapamil for 25 minutes. **Panel C,** effects of TTX on a different piece of myocardium taken from the same patient. Vertical calibration, 200 V/s for the upstroke velocity traces and 50 mV for the action potential recordings. Horizontal calibration, 4 ms for the upstroke velocity traces and 100 ms for the action potential recordings. Data obtained from Patient 6. See text for discussion.

middle of the trabeculum (X1), afterdepolarizations of progressively increasing amplitude developed after each of 5 action potentials elicited by intracellular current injection. The fifth stimulated action potential was followed by a series of triggered action potentials that terminated with a gradual increase in cycle length and a subthreshold afterdepolarization.

Stimulated or triggered action potentials at site X1 did not propagate to other recording sites approximately 4 mm proximal or distal to X1 (sites X2 and X3), nor did triggered activity at X2 or X3 propagate to X1 or to recording sites immediately adjacent to the infarcted myocardium. An example of the lack of interaction between sites X1 and X2 is shown in Figure 8B. Spontaneous activity at X1 triggered by 2 stimulated action potentials produced no response at X2 and the subsequent triggering of action potentials at X2 did not alter existing activity at X1.

**Pacemaker modulation and annihilation:** Modulation of pacemaker activity by subthreshold depolarizing and hyperpolarizing pulses was studied in 3 preparations. Pulses delivered early in the spontaneous cycle delayed the next expected discharge, whereas those delivered later in the cycle accelerated the subsequent discharge. In the preparation shown in Figure 9A, injection of a subthreshold current pulse through the lower microelectrode relatively early in the spontaneous cycle (approximately 680 ms after initiation of the rapid portion of the preceding action potential upstroke; indicated by the left dot) produced a subthreshold depolarization in the upper record and delayed the next spontaneous discharge by 400 ms. A current pulse of the same intensity and duration delivered later in the spontaneous cycle (950 ms after the preceding upstroke; the right dot) accelerated the next discharge by 210 ms, relative to the previous 2 action potentials. This pattern of pacemaker modulation resembled previously described phase resetting patterns in other models of biologic oscillators.[11,17] Theoretic predictions from these models indicate that spontaneous activity can be annihilated by a pulse delivered at a critical phase of the pacemaker cycle, known as the singular point.[17] In accordance with these predictions, we found that pulses delivered at the singular point (in this example 930 ms after the preceding action potential upstroke) abolished pacemaker activity and this effect persisted for at least the next 2 minutes (Fig. 9B).

Single subthreshold pulses also could alter the character of subsequent spontaneous action potentials. The example shown in Figure 9C illustrates that an appropriately timed current pulse converted bimodal action potentials to action potentials with a single active component followed by a subthreshold early afterdepolarization. The presence of delayed afterdepolarizations (indicated by the arrows) after the change in action potential configuration suggests that summation of these potentials and the early afterdepolarization accompanying each spontaneous action potential may have been responsible for the second upstroke component of the bimodal action potentials.

**Effects of tetrodotoxin and verapamil:** The spontaneously active preparation shown in Figures 5 and 6 was exposed to tetrodotoxin ($5 \times 10^{-6}$ *M*) for 15

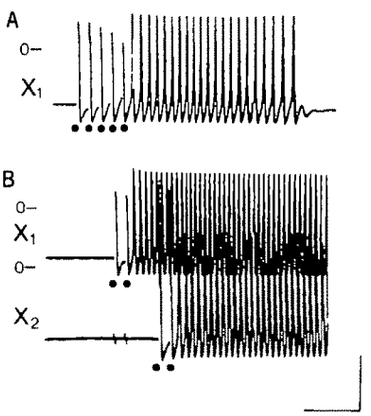

**FIGURE 8.** Triggered sustained rhythmic activity in diseased human ventricle. **Panel A,** sustained rhythmic activity triggered by a series of driven action potentials (indicated by the dots) at recording site X1. **Panel B,** initiation of triggered activity at sites X1 and X2 along the same trabeculum by intracellular current injection (indicated by the dots beneath the respective action potential recordings). For current pulses, cycle length is 2,000 ms, pulse duration 10 ms, and pulse intensity 200 nA. Vertical calibration, 50 mV; horizontal calibration, 10 seconds. Data obtained from Patient 5. See text for discussion.

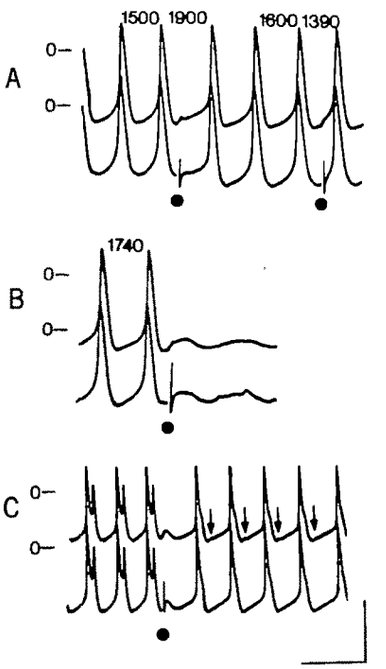

**FIGURE 9.** Modulation of pacemaker activity in diseased human ventricle by subthreshold current pulses. **Panel A,** 2 recording sites along the same trabeculum in a spontaneously active preparation. Current pulses of 30 ms in duration were injected through the lower microelectrode (**dots**). The interval between spontaneous action potentials is given in milliseconds above each interval. **Panel B,** same cells and current pulse variables as in **panel A. Panel C,** 2 recordings from a different area of the same preparation during spontaneous activity. The **dot** indicates the injection of a 30 ms current pulse and the **arrows** indicate delayed afterdepolarizations. Vertical calibration, 50 mV; horizontal calibration, 2 seconds in **A and B** and 4 seconds in **C.** Data obtained from Patient 5. See text for discussion.

minutes, followed by 30 minutes of washout, and was then exposed to verapamil ($2 \times 10^{-6}$ *M*) for 45 minutes (Fig. 10). Tetrodotoxin completely suppressed action potentials at the recording site after 10 minutes. Verapamil suppressed action potentials after 15 minutes, but low level oscillations remained. These gradually decayed over the next 45 minutes and the preparation became completely quiescent.

## Discussion

The results of this study indicate that cells with normal and abnormal action potentials existed in pieces of resected human myocardium that appeared to participate in the initiation of ventricular tachycardia at surgery. Tetrodotoxin, but not verapamil, suppressed action potentials in some abnormal cells whereas verapamil, but not tetrodotoxin, suppressed action potentials in other abnormal cells. Both groups of cells were found in areas of depressed conduction and may have contributed to the entrance and exit block, unidirectional and bidirectional block, Wenckebach-type periodicity, and summation observed in vitro. In addition, both tetrodotoxin and verapamil suppressed spontaneous activity in some preparations, suggesting that depressed fast responses and slow responses played a role in abnormal impulse formation. Subthreshold potentials induced by current injection or action potentials proximal to a zone of block altered the spontaneous discharge rate of automatic cells, annihilated pacemaker activity, and influenced the configuration of spontaneous action potentials. Afterdepolarizations following stimulated action potentials occasionally reached threshold and triggered bursts of sustained rhythmic activity.

The cellular electrophysiologic abnormalities cited herein were assumed to be related to the underlying heart disease of these patients. However, all patients had received cardioactive drugs at some point in their therapy and some patients had received antiarrhythmic agents just before or at the time of surgery (Table I). These drugs may have contributed to the in vitro electrophysiologic findings. Therefore, our results pertain to the potentially arrhythmogenic electrical properties of these preparations, regardless of the precipitating factor, rather than to the electrical properties of diseased ventricle per se.

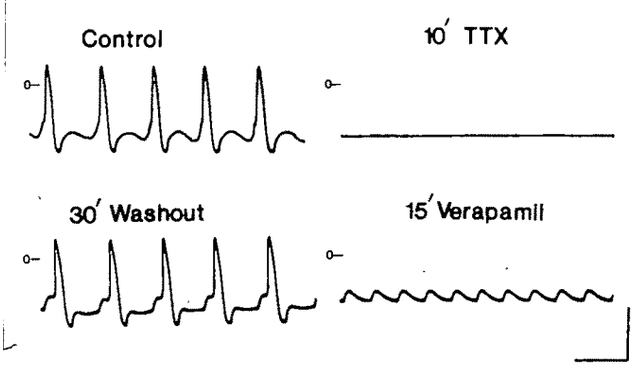

**FIGURE 10.** Effects of tetrodotoxin and verapamil on spontaneous activity in diseased human ventricle. **Upper panels,** automaticity before (Control) and after superfusion with TTX ($5 \times 10^{-6}$ *M*) for 10 minutes. **Lower panels,** automaticity after 30 minutes of washout of TTX and after superfusion with verapamil ($2 \times 10^{-6}$ *M*) for 15 minutes. Vertical calibration, 50 mV; horizontal calibration, 2 seconds. Data obtained from Patient 4. See text for discussion.

**Abnormal action potentials and conduction:** The relatively low resting membrane potential of most cells in diseased myocardium may underlie many of the abnormal action potential characteristics of these cells and the slow and frequently dysynchronous conduction in infarcted myocardium. Sustained depolarization partly inactivates fast inward sodium channels, decreasing excitability, action potential upstroke velocity, and conduction velocity.[23,25] These phenomena may contribute to the development of graded responses and summation.[26] However, we (Fig. 1) and others[1,27] recorded action potentials that had variable amplitudes in cells with nearly normal resting potentials, indicating that a normal resting potential was not necessarily associated with normal active membrane properties.

Cells with variable action potential responses to different stimulus intensities and frequencies often exhibited Wenckebach-type block. Wenckebach cycles have been postulated to involve decremental conduction culminating in block or step delays in conduction at a junction of partly refractory tissue.[18,19] The records in Figures 1 and 6 tend to support the latter concept, because the foot potential input after each stimulus was constant in amplitude, but successive action potentials were delayed in onset until block occurred. The activation delay presumably was due to increasing refractoriness produced by the progressively shorter interval between complete repolarization and the succeeding stimulus.

**Depressed fast responses and slow responses:** The suppression of action potentials and automaticity by both verapamil and tetrodotoxin suggests that depressed fast responses and slow responses coexist in diseased human ventricle and participate in abnormal impulse generation and propagation. However, we could not record from all cells in a preparation or be certain that we had impaled the dominant pacemaker cell in an ectopic area. Therefore, it is possible that tetrodotoxin or verapamil only appeared to suppress action potentials or automaticity, when they actually had produced entrance or exit block from the stimulating electrode or ectopic focus. This possibility is suggested by Figure 10B, in which verapamil initially suppressed action potentials in the recording zone, but low level oscillations remained. These potentials may have been intrinsic membrane oscillations of the recorded cell or may have been subthreshold responses to ongoing spontaneous activity in another area of the preparation. However, the eventual cessation of the low level potentials suggests that verapamil did suppress automaticity in this case.

**Automaticity:** The phase-response relation, annihilation, and alteration of action potential configuration produced in spontaneously depolarizing preparations by subthreshold and regenerative action potentials resembled that produced in in vitro models of depressed conduction.[10–13] Our observation that these phenomena can occur in diseased human ventricular myocardium

supports previous contentions that this type of oscillatory phenomenon has clinical relevance.[10,28] For example, the spontaneous discharge rate of an ectopic ventricular focus may be modulated by changes in the sinus rate and produce complex, but predictable, ventricular rhythms.[28] Sinus complexes or external stimuli that invade a spontaneously discharging region of myocardium at the appropriate time (the singular point[17]) could terminate ventricular ectopy through annihilation. The mechanism by which annihilation occurs in cardiac tissue has not been defined, but the singular point and annihilation appear to be features of several types of biologic oscillators.[11,17] Appropriately timed impulses also might change the electrocardiographic manifestation of polymorphic ventricular tachycardia[29] from 1 configuration to another, as suggested by Figure 9C. Furthermore, termination of ventricular tachycardia with a single premature stimulus could reflect annihilation of an automatic focus, rather than interruption of a reentrant pathway.

Triggered sustained rhythmic activity also may be initiated and terminated by a single stimulus.[14–16] The records in Figure 8 illustrate that this type of activity can occur in virtual isolation from surrounding myocardium, raising the possibility that in the intact heart triggered pacemakers may "control" small areas of myocardium without producing manifest ventricular arrhythmias. These findings may relate to the observation that triggered activity was seen in damaged rat myocardium in vitro at a time when no arrhythmias were apparent on the surface electrocardiogram.[22]

**Acknowledgment:** We thank Drs. Robert D. King and John W. Brown, Department of Surgery, Indiana University School of Medicine, for their assistance during the mapping procedure and for performing the aneurysmectomies and endocardial resections, and Nancy S. Lineback for preparing the manuscript.

# Biphasic Nature of Propranolol's Microelectrophysiologic Effects

DAVID H. S. IANSMITH, MD, PhD, CLINTON B. NASH, PhD, and JACK P. BANDURA, MD, PhD

**The microelectrophysiologic effects of d,l-propranolol were observed to be biphasic when a wide range of concentrations was used in canine atrial tissue; therefore, the 2 isomers were used separately to test the hypothesis that the opposite effects of propranolol could be separated by isomeric isolation. Whole atria were detached from dog hearts and 3 by 0.5 cm strips were cut from the atria. Transmembrane action potentials were monitored from the atrial strips mounted in an isolation chamber containing Tyrode's solution. Concentrations of d-propranolol, l-propranolol, and the d,l-racemate ranging from 0.03 to 1.0 μg/ml were added to the bath and the effects observed for 60 minutes. In lower concentrations d,l-propranolol decreased the effective refractory period and activation time while increasing maximal rise velocity, action potential amplitude, and resting membrane potential. Higher concentrations produced the opposite effects. The l-isomer produced effects very similar to those of the lower concentrations of the racemate, whereas the d-form mimicked those effects of the higher concentrations of the racemic mixture. We conclude that d,l-propranolol is capable of exerting 2 opposite electropharmacologic actions, which may be demonstrated by varying the concentration of d,l-propranolol or by separating the isomers.**

The first beta-adrenergic blocking agent introduced by Powell and Slater[1] in 1958 was heralded as a major scientific and clinical tool. The later synthesis of propranolol introduced a clinically useful beta-blocking drug[2] that has rapidly become one of the most versatile and widely used chemotherapeutic agents of the day.[3]

Although the antiarrhythmic mode of action of propranolol is not fully established, 2 categories of action are often suggested: (1) specific antagonism of adrenergically induced arrhythmias at a receptor level, and (2) a quinidine-like, nonspecific, membrane-depressant, antiarrhythmic action.[4]

In a previous study,[5] the microelectrophysiologic effects of propranolol on canine isolated atrial tissue were observed to be opposite at ranges of effective clinical concentrations. The question thus arose as to whether both of these actions, that is, beta blockade and membrane depression, might be demonstrable, depending on the physiologic situation and the effective concentrations. To examine this possibility, we attempted to dissect these actions of propranolol by examining the 2 isomeric forms of the drug.

## Methods

After anesthetization with intravenous pentobarbital sodium (30 mg/kg), the chest of adult dogs was opened through a right thoracotomy; the heart was visualized and rapidly removed. The left atrium was separated from the heart and submerged in a beaker of warmed, oxygenated Tyrode's solution. Rinsed clean of blood, the atrium was opened flat, and 3 by 0.5 cm strips were sectioned by cutting along the recessed regions between trabeculae. Each tissue sample was pinned to the paraffin floor of the 3 ml well of a lucite isolation chamber. By a system of pumped inflow and suctioned outflow, oxygenated 36°C Tyrode's solution continuously superfused the tissues at a rate of 2 ml/min. A stimulating electrode was placed on the anatomically proximal end of the tissue sample and provided double the threshold drive stimulation at a rate of 80 beats/min. A bipolar surface electrode was positioned on the distal end of the tissue for monitoring tissue electrogenic viability, whereas 2 potassium-filled, glass microelectrodes were used to impale 2 cells, separated by no more than 0.5 cm, for recording the transmembrane action potentials.

After a 30-minute equilibration period, a control photograph of the oscilloscope tracing, bearing 2 action potentials,

fast tracings of their phase O upstrokes, and a surface electrogram was taken. After establishment of the effective refractory period by the electronic, time-delayed manipulation of an extrastimulus interpolated between 2 drive stimuli, the superfusion medium was changed from normal Tyrode's solution to a drug-containing Tyrode's solution, and a timing device started. At 15-minute intervals, photographic records and effective refractory period determinations were obtained during 60 minutes of drug perfusion. The same 2 cells were monitored for the entire period of study. Each tissue sample was administered a single drug treatment at 1 concentration. At times of photographic recordings or at points of interest between, the oscilloscopic tracings were also monitored and stored on a tape recorder.

After 60 minutes of drug treatment, the bathing medium was restored to normal Tyrode's solution for 30 minutes to allow for tissue recovery and a final data sampling.

Dose-response relations were established for the 6 microelectrophysiologic variables of effective refractory period, activation time, action potential amplitude, resting membrane potential, action potential duration at 90% repolarization, and maximal rise velocity of phase O depolarization, using the racemic mixture of propranolol as well as each of the isomers separately, in concentrations ranging from 0.03 to 1.0 μg/ml.

## Results

An interesting contrast is produced by comparison of the dose-response relations of the 3 forms of propranolol (d,l; d; and l) used in these atrial experiments. Figure 1 demonstrates this effect by characterizing the action of various concentrations of each form on atrial effective refractory period. Whereas the d-isomer increases refractoriness and the l-isomer mostly decreases ERP, the racemic mixture of the 2 is biphasic in its effect. In lower concentrations, the racemate acts like the l-isomer and reduces the effective refractory period, whereas in higher concentrations it acts like the d-isomer and increases refractoriness. The d,l and d forms show the classic dose-response relation, but the l form shows a fairly flat line that would suggest a plateau effect.

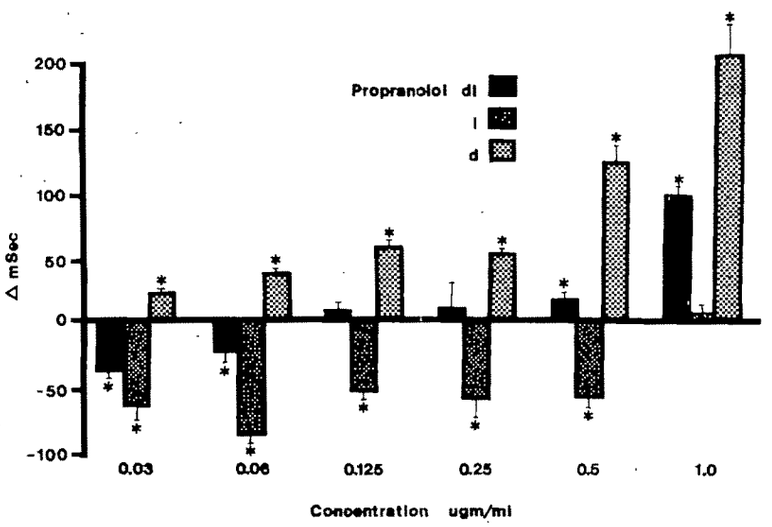

**FIGURE 1.** Comparison of the effects of d,l, d, and l-propranolol on atrial effective refractory period. **Each bar** represents the mean ± standard error. **Asterisks** indicate a significant difference from control ($p < 0.05$). See text for details.

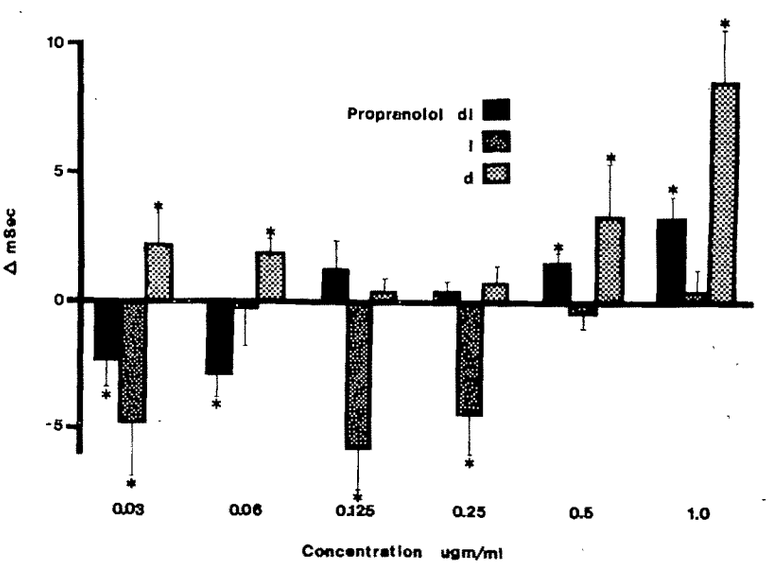

**FIGURE 2.** Effects of d,l-propranolol and the separate isomers on atrial activation time. See Figure 1 for explanation.

Figure 2 less dramatically indicates that atrial activation time is generally increased by the d-isomer, decreased by the l-isomer, and affected in both directions by the racemate, again showing the phenomenon of isomeric separation of action.

Maximal rise velocity of phase O also displays an impression of isomeric separation of action (Fig. 3). The d form tends to depress the measure, the l form may increase maximal rise velocity, and the racemic mixture fluctuates in both directions. A similar relation is seen in Figure 4 showing that lower concentrations of d,l-propranolol resemble the effects of the l-isomer by increasing the atrial action potential amplitude, whereas higher concentrations mimic the effects of the d-form by decreasing amplitude. The 0.125 to 0.25 μg/ml point on these curves repeatedly stands as the conversion position for the biphasic effects of the racemate. The relatively large standard errors that accompany the mean data from these concentrations also suggest a zone of transition.

Action potential duration and resting membrane potential were less consistently affected by these 3 forms of propranolol. A summary of the effects of propranolol's isomeric forms on the atrial potential is contained in Table I. Whereas the l- and d-isomers affect opposite actions, the racemic mixture of the 2 forms compromises the extremes by eliciting both actions, depending on the concentration administered.

**TABLE I General Effects of the Isomeric Forms of Propranolol on the Atrial Transmembrane Potential**

| | Refractory Period | Activation Time | Maximal Rise Velocity | Amplitude |
|---|---|---|---|---|
| l-propranolol | ↓ | ↓ | ↑ | ↑ |
| d,l-propranolol | ↓↑ | ↓↑ | ↑↓ | ↑↓ |
| d-propranolol | ↑ | ↑ | ↓ | ↓ |

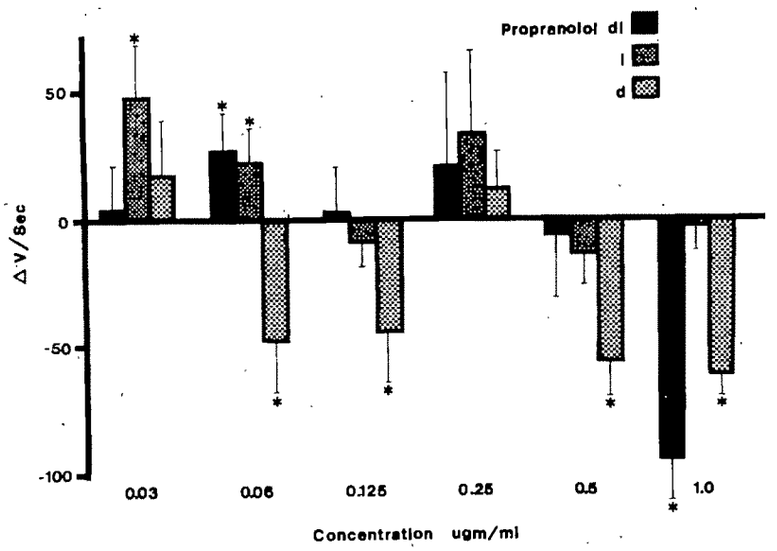

**FIGURE 3.** Effects of d,l-propranolol and the separate forms of the racemate on maximal rise velocity of phase O. See Figure 1 for details.

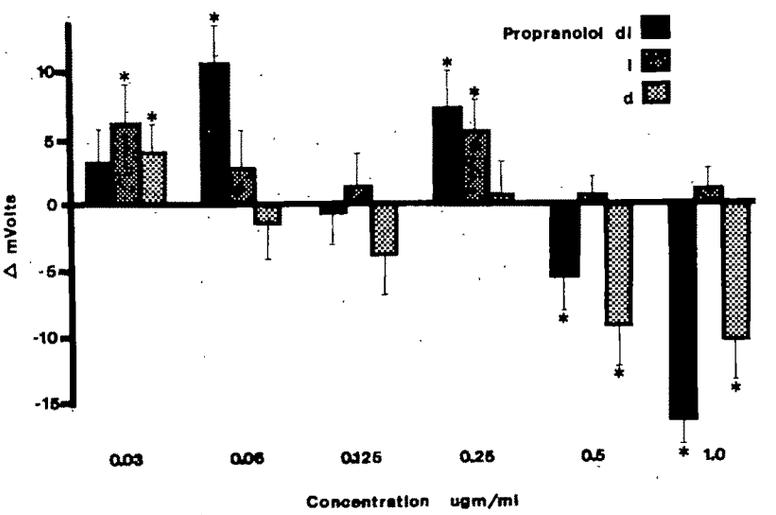

**FIGURE 4.** Response of atrial action potential amplitude to increasing concentrations of d,l, d, and l forms of propranolol. Details as in Figure 1.

## Discussion

The concentrations of propranolol used in this study (0.03 to 1.00 μg/ml) cover the range of blood levels of propranolol commonly found in clinical practice. Walle et al[6] established as a range of plasma concentrations 0.031 to 0.262 μg/ml in patients given 40 mg every 6 hours; Shand et al[7] reported peak plasma levels of 0.036 to 0.212 μg/ml from a single dose of 80 mg administered orally; Rao et al[8] studied patients chronically receiving 80 mg of propranolol every 6 hours and measured peak plasma levels of 0.125 to 0.621 and minimal levels of 0.059 to 0.55 μg/ml. Other investigators have reported similar values.[9–11]

The observations that propranolol exhibits a concentration-dependent, biphasic action on the atrial transmembrane potential, and that the separate administration of the agent's component isomers may effectively disjoin these 2 opposite sets of effects raise some interesting points. Reports conflict in their description of propranolol's microelectrophysiologic effects. Davis and Temte[12] and Vaughan Williams[13] recorded propranolol-induced alterations in the ventricular and atrial transmembrane potentials as minimally decreasing duration and only relatively prolonging refractoriness, but mainly acting to depress automatic phase 4 activity.[12,13] However, Rosen et al[14] reported that in antiarrhythmic concentrations, propranolol acted to significantly prolong duration and refractoriness, to depress rise velocity of the depolarization phase, and to decrease amplitude and resting potential, very similar to quinidine's effects on the ventricular transmembrane action potential.

In this study lower effective concentrations of d,l-propranolol shortened refractoriness and activation time, while increasing amplitude, resting potential, and maximal rate of rise of phase O. Higher concentrations accomplished the opposite, that is, refractoriness and activation time were prolonged, whereas amplitude, resting potential, and maximal rise velocity were depressed. The l-isomer of propranolol generally manifested those actions produced by the lower concentrations of the racemate, and d-propranolol, those of the higher concentrations of the racemic mixture. A logical conclusion from this interesting phenomenon is that in lower doses the action of propranolol is mainly that of beta-adrenergic blockade. This conclusion would be supported by the fact that these actions are duplicated by the l-isomer of propranolol, the form in which beta-blocking capacity is concentrated; that similar clinical concentrations only demonstrate beta blockade[15,16]; and that the flatness of the dose-response curves for the l-isomer reflects an already maximally established effect. An initial impression might be formed, considering the previously listed effects of the l-isomer, that they more resemble those of beta adrenergic agonist activity than of beta antagonism. Initial data from this laboratory suggest that the classically accepted electrophysiologic effects of the catecholamines are rate dependent, and that when administered in concentrations low enough (0.01 to 0.2 μg/ml) so that rate is unaffected and ectopy is absent, isoproterenol might increase refractoriness and slow conduction, while depressing resting potential, amplitude, and rate of rise of phase O. In higher concentrations, propranolol's beta-adrenergic blockade might be masked by the quinidine-like membrane depression known to be expressed by the d-isomer.[3]

These results, demonstrating propranolol's capacity to affect opposite electrophysiologic actions at the extreme ranges of effective concentration, might offer some explanation for propranolol's versatility as an antiarrhythmic agent. In lower concentrations, propranolol might disrupt a reentrant focus by improving conduction through a compromised region of tissue and converting retarded cellular characteristics, dependent on a slow inward current, to those that are more capable of operating by way of the fast sodium current. In higher concentrations, the agent could suppress dysrhythmias by further depressing a region of unidirectional block and of slow conduction to the point of complete block and inactivity. Thus, propranolol at different levels might be as efficacious for the treatment of a noncatecholamine-induced arrhythmia as for one produced by catecholamines.

*Conclusions:* The biphasic nature of propranolol's electrophysiologic actions may be effectively isolated by the separation of its 2 isomeric forms: the beta-blocking l-isomer eliciting the actions of the lower concentrations of the racemate, with the membrane depressant d-form demonstrating those effects of higher concentrations of the racemate. Thus, the concentration-dependent, biphasic microelectrophysiologic actions of the racemic form of propranolol might be used to explain its antiarrhythmic versatility.

# Cryosurgery for Cardiac Arrhythmias: Acute and Chronic Effects on Coronary Arteries

WILLIAM L. HOLMAN, MD, MASATOSHI IKESHITA, MD, ROSS M. UNGERLEIDER, MD, PETER K. SMITH, MD, RAYMOND E. IDEKER, MD, PhD, and JAMES L. COX, MD

**The use of cryosurgery near major coronary arteries for the treatment of supraventricular and ventricular tachyarrhythmias has caused concern over the possible deleterious acute and chronic effects of cryothermia on vessel patency and integrity. The present study was designed to examine both the acute and chronic effects of cryothermia on major coronary vessels in an experimental model that simulates clinical conditions. In the acute phase of the study, 10 dogs underwent direct cryothermic exposure of the left anterior descending (LAD) coronary artery while coronary artery flow and regional myocardial blood flow were calculated. Direct cryothermic exposure of the LAD resulted in total cessation of LAD blood flow 20 ± 4 seconds after institution of cryothermia. Arterial patency returned 29 ± 8 seconds after termination of cryothermic exposure. In the second phase of this study, 16 dogs had cryolesions applied directly over the LAD at myocardial temperatures of 37°C and during elective cardioplegic arrest at myocardial temperatures of 6 to 12°C. In addition, cryothermia was applied directly to the coronary sinus in these animals. The animals were allowed to live either 48 hours, 2 weeks, or 6 months after the initial procedure, and the cryolesions and underlying vessels were examined histologically. Although coronary arteriography at 6 months showed all coronary arteries to be patent, microscopic examination revealed coronary intimal hyperplasia to be present in the majority of the coronary arteries at the site of the cryolesion, particularly if the cryolesion had been applied during hypothermic, cardioplegic arrest. Cryothermia had no effect on the coronary sinus. This study provides evidence for cryothermia-induced coronary arterial damage that may produce hemodynamically significant coronary artery stenosis and suggests that caution be exercised when it is necessary to create cryolesions in the vicinity of major coronary arteries.**

Cryothermic ablation of myocardium has been advocated in a variety of surgical procedures for the management of both supraventricular and ventricular arrhythmias. Some of these procedures require the application of cryothermia in the vicinity of major coronary vessels. For example, the experimental left atrial isolation procedure[1] as well as cryothermic ablation of aberrant pathways of atrioventricular conduction[2] requires the use of cryothermia in the atrioventricular groove. In addition, cryothermic ablation of arrhythmogenic ventricular foci[3,4] may require exposure of coronary arteries to cryothermia. The use of cryosurgery near major coronary arteries has caused concern over the possible deleterious acute and chronic effects of cryothermia on vessel patency and integrity, particularly in view of previous reports of endothelial damage and intimal proliferation in both coronary[5] and noncoronary vessels[6–12] after cryothermic exposure. The purpose of this study was to examine the acute and chronic effects of cryothermia on coronary vessels in an experimental model that simulates clinical conditions and to make recommendations concerning the use of cryothermia near major coronary arteries.

## Methods

**Experimental protocol for evaluating the acute effects of cryothermia on major coronary arteries:** Ten adult mongrel dogs weighing 24 to 26 kg were anesthetized with sodium pentobarbitol (30 mg/kg), and ventilated with room air through a cuffed endotracheal tube attached to a Harvard pump respirator. Percutaneous cannulations of the femoral

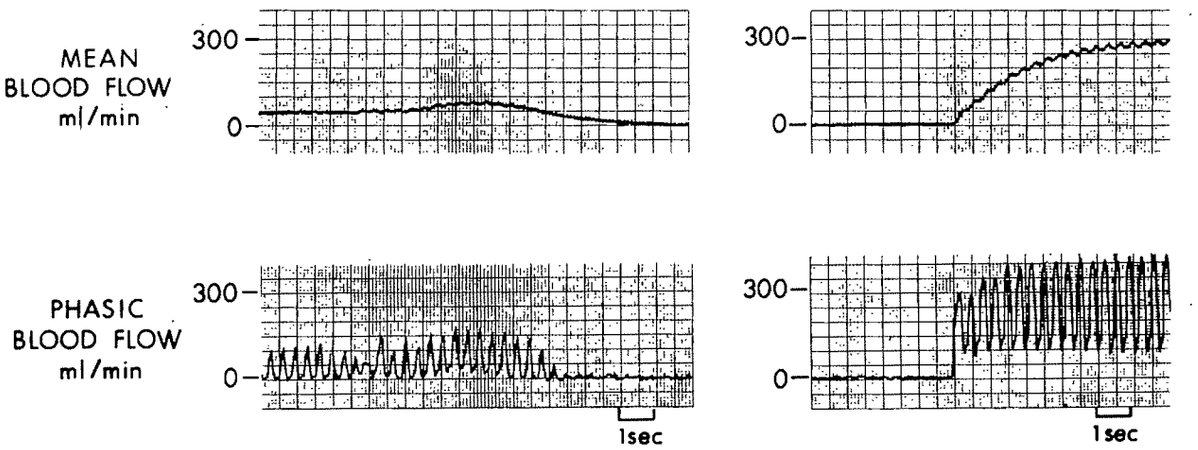

**FIGURE 1.** LAD coronary artery blood flow during direct cryothermic exposure (**left panels**) and at the time of thawing 29 ± 8 seconds after termination of cryothermic exposure (**right panels**). Coronary artery occlusion occurred an average of 20 ± 4 seconds after initiation of cryothermic exposure.

artery and vein were performed to monitor systemic arterial blood pressure and pulmonary artery pressure by way of a Swan-Ganz catheter. The heart was exposed through a left thoracotomy and a pericardial cradle was constructed. A 1 cm portion of the proximal LAD coronary artery was dissected free of surrounding connective tissue and fitted with a 2.5 mm Howell electromagnetic flow probe (Howell Instruments, Camarillo, California). The flow probes were connected to a Model HMS 1000 Howell flow meter and the signals were passed through 2 Hewlett-Packard Model 8802-A medium-gain amplifiers at filter settings of 30 Hz (phasic trace) and 1.0 Hz (mean trace). Systemic arterial blood pressure, pulmonary artery pressure, mean LAD coronary blood flow, phasic LAD coronary blood flow, and a standard lead II electrocardiogram were recorded on magnetic tape at 3¾ in/s.

Regional myocardial blood flow in the subepicardium, mid-myocardium, and subendocardium of various regions of the LAD vascular bed and of the circumflex coronary artery vascular bed was determined by the radioactive microsphere technique at the study intervals outlined below. The radioactive tracer microspheres were 8 to 10 μm in diameter and were labelled with cerium-141, iodine-125, strontium-85, or scandium-46. A total of 400,000 to 800,000 microspheres were given per injection through a left atrial catheter. A reference sample of femoral arterial blood was withdrawn at a constant rate for 2 minutes beginning 15 seconds before each microsphere injection. This allowed calculation of blood flow to a given region of myocardium in ml/g/min. The radioactive counts for each nuclide in each tissue and blood specimen were determined on a Beckman gamma 4000 scintillation counter containing a 2 inch sodium iodide crystal and employing a digital printout. Overlap for photopeaks in the same tissue specimen was corrected by the method of Rudolph and Heymann.[13]

After the heart had been instrumented, a control radioactive microsphere injection was made and control LAD blood flow, systemic arterial pressure, pulmonary artery pressure, and electrocardiographic data were obtained. A 4 mm cylindrical cryoprobe (Frigitronics, Shelton, Connecticut) cooled to −60°C with expanding nitrous oxide was applied to the LAD immediately distal to the site of the electromagnetic flow

* $p < 0.05$.

Column 1 represents control myocardial blood flow, column 2 the myocardial blood flow after 60 seconds of direct cryothermic (CT) exposure of the LAD, column 3 the myocardial blood flow 15 minutes after reactive hyperemia, and column 4 the myocardial blood flow after mechanical occlusion of the LAD coronary artery at the site of previous cryothermic exposure.

ENDO = subendocardium; EPI = subepicardium; LAD = vascular bed of the left anterior descending coronary artery distal to the site of either cryothermic exposure or of mechanical occlusion; LCA = vascular bed of the left circumflex coronary artery; L/L = myocardium in the region of the border of the left circumflex and LAD vascular beds; MID = mid-myocardium; PLAD = LAD vascular bed proximal to the site of cryothermic exposure or mechanical occlusion; RH = reactive hyperemia.

probe for 180 seconds. The cryoprobe was applied gently enough so that similar application of a warm cryoprobe produced no change in LAD coronary flow as determined by the electromagnetic flow probe. After 60 seconds of cryothermic exposure, a second radioactive microsphere injection into the left atrium was performed. After the cryothermic exposure was completed, the LAD coronary artery was allowed to thaw, and 15 minutes after the onset of reactive hyperemia a third injection of radioactive microspheres was performed. Thirty minutes later, the LAD coronary artery was occluded with a small vascular clamp at the site of previous cryothermic occlusion for a period of 180 seconds. The fourth injection of radioactive tracer microspheres was performed 60 seconds after application of the LAD occlusive clamp. Regional myocardial blood flow data obtained during this mechanical occlusion of the LAD coronary artery were compared with regional myocardial blood flow data obtained during the period of cryothermic exposure of the LAD. Measurements of heart rate, systemic and pulmonary artery blood pressure, phasic and mean LAD coronary artery flow, regional myocardial blood flow in the areas described above, and the times from the beginning of cryothermic exposure to LAD occlusion and to return of LAD coronary flow for each intervention were obtained for analysis.

**Experimental protocol for evaluating the chronic effects of cryothermia on major coronary arteries:** Sixteen adult mongrel dogs weighing 24 to 26 kg were anesthetized with sodium pentobarbitol (30 mg/kg), and ventilated with 40% oxygen through a cuffed endotracheal tube attached to a Bennett MA-1 volume-cycled respirator. Sterile percutaneous cannulations of the femoral artery and vein were performed to monitor systemic arterial blood pressure and pulmonary artery pressure by way of a Swan-Ganz catheter. A sterile left lateral thoracotomy was performed, and the right atrium and ascending aorta were cannulated for cardiopulmonary bypass. Asanguineous priming solution and Shiley Model 100-A bubble oxygenators were used in all experiments. During cardiopulmonary bypass, the animals were perfused at 2.25 to 2.50 liters/min/$m^2$, maintaining a mean arterial perfusion pressure of 70 to 90 mm Hg. A thermistor (Instrumentation Laboratories, Boston, Massachusetts) was placed in the ventricular septum to monitor myocardial temperature. After institution of normothermic (37°C) cardiopulmonary bypass, the 4 mm cylindrical cryoprobe was applied to the proximal portion of the LAD coronary artery for 120 seconds at −60°C. The aorta was then cross-clamped and 300 ml of 4°C lactated Ringer's solution with 20 mEq potassium chloride/liter was infused into the aortic root, achieving cardioplegic arrest at a myocardial temperature of 6 to 12°C. A cryolesion was then placed over the distal LAD coronary artery and, in addition, a cryolesion was created over the coronary sinus in the posterior left atrioventricular groove. The cryolesions applied during cardioplegic arrest were performed in exactly the same manner as the one that was applied before cardioplegic arrest. The aortic cross-clamp was then released and the heart was defibrillated, and after rewarming to a ventricular septal temperature of 37°C, the animal was weaned from cardiopulmonary bypass. Before closure of the chest, stainless steel suture material was placed at the edges of each cryolesion for later identification. The animals were killed at either 48 hours, 2 weeks, or 6 months after surgery. In the animals that were allowed to live for 6 months after surgery, coronary arteriography was performed before they were killed.

At postmortem examination, the hearts were removed and the coronary arteries were examined grossly before obtaining tissue blocks of the 2 cryolesions containing sections of the LAD coronary artery. A tissue section of coronary artery not involved in a cryolesion was obtained as a control in each animal. After fixation, 8 $\mu$m sections of the coronary arteries were stained with hematoxylin and eosin, Verhoeff-van Gieson, and Masson's trichrome stains. The sections of coronary artery were examined by an independent cardiac pathologist (REI) in a single-blind fashion. The LAD coronary artery and the coronary veins were graded for degree of stenosis on a percent basis with 100% representing total occlusion. A series of other pathologic variables were graded on a scale of 0 to 4 with 0 representing absence of each variable, and 4 representing the maximal possible involvement. The variables recorded were (1) inflammation of the coronary artery adventitia, media, and overlying epicardium; (2) disruption of the coronary artery media; (3) disruption or proliferation of the coronary artery intima; (4) disruption of the internal elastic lamina; (5) calcium deposition in the arterial wall; and (6) alteration of coronary venous architecture. Coronary vessels without surrounding myocardial necrosis or fibrosis attributable to cryothermic injury were excluded from analysis. The pathologic examination of the coronary sinus was limited to a gross description, although stained microscopic sections were obtained.

## Results

**Acute effects of cryothermia on coronary arteries:** Direct cryothermic exposure of the LAD coronary artery invariably resulted in acute occlusion of the coronary artery, although none of the frozen arteries ruptured or showed noticeable dilatation after thawing. Microscopic hemorrhage within the adventitia of the coronary artery at the site of cryothermic exposure was the only immediate pathologic change detected in the coronary arteries and was prominent only after multiple cryothermic exposures at the same site. Mean LAD coronary artery flow before cryothermic exposure was 60 ± 6 ml/min, and typically decreased from that control range to 0 ml/min during the period of cryothermic application (Fig. 1). Coronary artery occlusion occurred 20 ± 4 seconds after institution of cryothermia and arterial patency returned 29 ± 8 seconds after termination of cryothermic exposure. The return of coronary artery blood flow was sudden and typically increased to levels above 300 ml/min at the peak of reactive hyperemia (Fig. 1). During the period of coronary artery occlusion secondary to the cryothermia, the myocardium distal to the cryolesion became dyskinetic and cyanotic, but the tissue regained normal color and contractile activity rapidly after restitution of coronary blood flow with thawing. There was no statistically significant difference between measurements of heart rate before and after cryothermia (152 ± 5 versus 156 ± 5 beats/min, respectively), systemic blood pressure (141/95 versus 136/89 mm Hg), or pulmonary artery diastolic pressure (11 ± 2 versus 11 ± 2 mm Hg). Regional myocardial blood flow data were analyzed for evidence of distal embolization of vascular debris after coronary artery freezing and thawing and also served to verify that cryothermic exposure directly over the LAD coronary artery had caused total occlusion as indicated by the electromagnetic flow probe tracing. These data are summarized in Table I.

Comparisons for statistical significance within each group were made using Student's $t$ test for paired data. Sixty seconds after initiation of cryothermia or mechanical coronary artery clamping, there was a statis-

tically significant decrease in myocardial blood flow to all layers of the LAD vascular bed distal to the site of the occlusion. The peripheral areas of the left circumflex coronary vascular bed also demonstrated a significant decrease in myocardial blood flow at that time. A concomitant increase in myocardial blood flow occurred in the myocardium of the LAD vascular bed proximal to the cryolesion as well as in most of the vascular bed of the left circumflex coronary artery. Myocardial blood flow returned to control levels in all vascular beds by 15 minutes after LAD freezing.

**Chronic effects of cryothermia on coronary arteries:** All coronary arteries subjected to cryothermia were grossly patent at examination 48 hours, 2 weeks, and 6 months after cryothermic exposure. In addition, no coronary artery stenoses were detectable at the cryolesion sites on biplane cineangiography 6 months after cryothermic exposure. The cryolesions created during hypothermic, cardioplegic arrest appeared larger than the cryolesions created at 37°C, an observation consistent with our previous findings.[14]

A summary of the histologic data is presented in Table II. Forty-eight hours after direct cryothermic exposure, the coronary arteries showed a mild degree (0.4 to 1.0) of inflammation in the overlying epicardium, the adventitia, and the media (Fig. 2). In addition to the presence of inflammation, the nuclei of smooth muscle cells in the arterial media were pyknotic and there was mild disruption of the arterial intima in 1 animal associated with noncircumferential fibrin deposition in the area of intimal discontinuity. In 3 animals. there was evidence of coronary venous occlusion, ranging from 25 to 100% in addition to minimal signs of fragmentation of the internal elastic lamina. The LAD coronary artery was patent at 2 weeks in all animals, although there was complete occlusion of a diagonal branch in 1 animal in which the cryolesion had been created during hypothermic, cardioplegic arrest (Fig. 3). By 2 weeks after cryothermic exposure, inflammation of the adventitia and media had cleared, but there was persistence of mild inflammation of the epicardium overlying the coronary artery at the site of cryothermic exposure. Moreover, the architecture of the coronary artery media had returned to normal by 2 weeks, while the coronary artery intima in 3 animals showed mild hyperplasia. Only minimal pathologic alterations were noted in the coronary veins at 2 weeks after cryothermic exposure.

The LAD coronary artery was patent in all animals 6 months after cryothermic exposure. However, LAD stenosis due to intimal hyperplasia was detected at the site of 4 cryolesions that had been created during hypothermic, cardioplegic arrest. The degree of stenosis in these 4 specimens ranged from 10 to 60%, and in 2 specimens the intimal hyperplasia was concentric (Fig. 4). In addition, 2 separate diagonal branches within the cryolesions showed 80% stenoses at 6 months (Fig. 5 and 6). Mild degrees of epicardial, adventitial, and medial inflammation were seen, and there was persistent mild fragmentation of the internal elastic lamina. Only 4 coronary arteries were judged completely normal at the

site of the cryolesion 6 months after cryothermic exposure. Three of these cryolesions had been created at a myocardial temperature of 37°C and 1 had been created during hypothermic, cardioplegic arrest. No stenosis, thrombosis, or vessel wall abnormality was seen in the coronary sinus at the site of cryothermic exposure 48 hours, 2 weeks, or 6 months after the procedure.

## Discussion

The first series of experiments in this study defined the acute changes in coronary artery blood flow during and immediately after the direct exposure of a coronary artery to cryothermia. The coronary arterial wall remained intact despite multiple exposures to cryothermia and did not develop acute aneurysmal dilatation. Complete cessation and resumption of coronary artery blood flow occurred promptly after the beginning and end of cryothermia, with a typical reactive hyperemic response occurring after the resumption of coronary flow. Regional myocardial blood flow data were obtained as a possible means of detecting distal coronary embolization of debris after thawing of the frozen vessel. These data indicate that freezing of major coronary arteries causes no such acute embolization. Thus, it appears that the immediate limiting factor in the use of cryothermia near major coronary arteries is the level of acute but reversible ischemia that can be tolerated in the myocardial tissue distal to the site of the transient cryothermic occlusion.

The long-term effects of direct cryothermic application to coronary arteries and to other large arteries including the aorta, hepatic artery, femoral artery, and carotid artery have been studied previously.[5,8–12] In

Each group of survivors had cryothermic exposure of major coronary arteries at both 37°C and during cardioplegic arrest at 6 to 12°C. Arterial and venous stenosis was graded on a percent basis from 0 to 100%, with the latter representing total occlusion. Qualitative parameters of vascular injury were graded on a scale of 0 to 4, with 0 representing absence of the parameter.

Art stenosis = degree of arterial stenosis; Ca dep = calcium deposition in the arterial wall; CP = cryolesions created in the arrested nonperfused heart at 6 to 12°C; IEL = disruption of the internal elastic lamina; Inf adv = inflammation of the adventitia; Inf epi = inflammation of the epicardium; Inf med = inflammation of the media; Intima = disruption or proliferation of coronary artery intima; Media = cell death or disruption of normal media; Ven dis = disruption of the venous architecture; Ven stenosis = degree of venous stenosis; 37°C = cryolesions created in the perfused beating heart at 37°C.

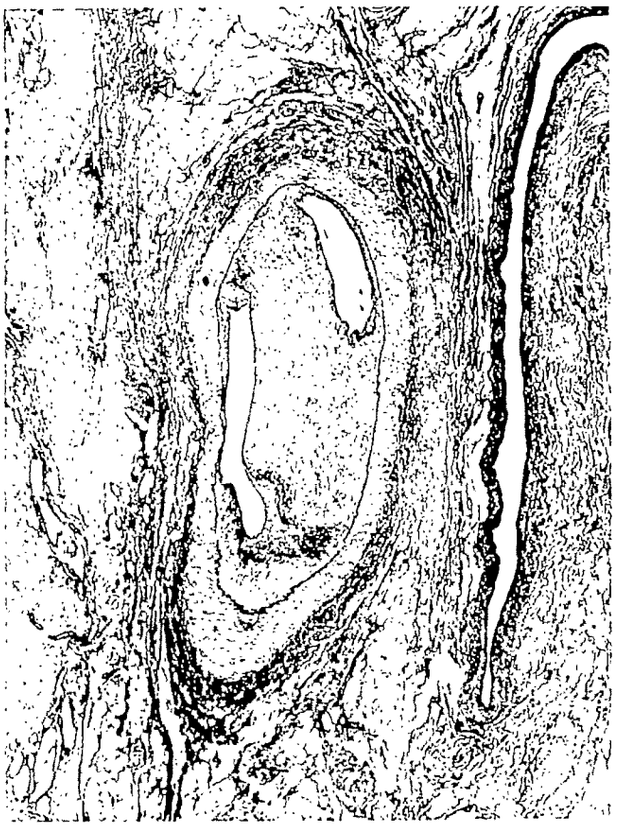

**FIGURE 5.** Diagonal branch of the LAD coronary artery (Verhoeff-van Gieson stain) 6 months after cryothermic exposure; the darkly stained internal elastic lamina marks the boundary of the markedly hyperplastic intima. (Magnification X40.)

**FIGURE 6.** Diagonal branch of the LAD coronary artery (Verhoeff-van Gieson stain) 6 months after cryothermic exposure; note the marked intimal hyperplasia similar in severity to that seen in Figure 5. (Magnification X40.)

addition, several studies have described the response of capillary endothelium to milder cryothermic exposure such as frostbite.[6,7] Those studies indicate that cryothermic exposure destroys cellular elements in the arterial wall but spares noncellular structural elements of the vessel wall. Capillary networks are destroyed by cryothermic injury, but larger arteries, such as those the size of major coronary arteries, continue to function as conduits for blood after thawing. Smooth muscle cells in the media of these arteries rapidly regenerate during the healing phase, while the intima often develops marked hyperplasia. The intimal hyperplasia has been shown to regress within 1 year after the cryothermic exposure[9]; however, if the hyperplasia was sufficiently severe, it could lead to impairment of coronary blood flow resulting in distal myocardial ischemia or infarction. The degree of intimal hyperplasia seen in cryolesions created under cardioplegic arrest in the present study progressed up to 6 months after the procedure, at which time intimal hyperplasia had produced mild to moderate stenosis of the coronary arteries. Coronary intimal hyperplasia appeared to be less severe when cryolesions were applied to the coronary arteries during normothermic perfusion, and these changes had regressed within 6 months after cryosurgery. The larger cryolesion size, and presumably more intense cryothermic exposure during cardioplegic arrest, is the most likely cause for this increased intimal hyperplasia. Of greater concern was the incidental discovery of occlusion or severe stenosis of diagonal branches of the LAD 2 weeks and 6 months postoperatively. This finding supports the recent study of Giampapa et al[10] describing the time-course of occlusion of small arteries and arterioles after cryothermia. These investigators found that the smallest vessels studied (0.33 mm in diameter) were permanently occluded immediately after cryothermia, while arteries 1.0 to 1.5 mm in diameter remained patent for up to 120 hours after cryothermic exposure.

The data obtained in the present study provide evidence for cryothermia-induced coronary arterial damage that may produce hemodynamically significant coronary stenosis. Therefore, caution should be exercised when one finds it necessary to create cryolesions in the vicinity of major coronary arteries. Furthermore, branches of these arteries (that is, coronary arteries <1.5 mm in diameter) should not be included in the cryolesion at all since they may become totally occluded postoperatively. If it is necessary to apply a cryolesion in the atrioventricular groove, for example when performing a left atrial isolation procedure or when ablating an accessory atrioventricular connection, an effort should be made to dissect a segment of the coronary artery free from the atrioventricular groove fat pad and to retract it away from the proposed site of cryothermia

application. If retraction of the coronary artery proves to be too hazardous and creation of a cryolesion is essential to the procedure, the cryolesion should be applied in the perfused heart rather than during elective cardioplegic arrest. Additionally, it is possible that the large amount of fat that surrounds coronary arteries within the atrioventricular groove provides an extra measure of protection since fat is a poor conductor of heat energy. The present study indicates that such dissection and retraction of the coronary sinus is not essential since direct application of cryothermia to the coronary sinus does not cause chronic occlusion or stenosis.

# Intravenous Amiodarone in the Acute Treatment of Recurrent Symptomatic Ventricular Tachycardia

FRED MORADY, MD, MELVIN M. SCHEINMAN, MD, EDWARD SHEN, MD, WILLIAM SHAPIRO, MD, RUEY J. SUNG, MD, and LORENZO DiCARLO, MD

**Fifteen patients aged 59.3 ± 11.5 years (mean ± standard deviation [SD]) had recurrent symptomatic ventricular tachycardia (VT) refractory to at least 2 conventional antiarrhythmic drugs. All patients had organic heart disease; 4 had an acute myocardial infarction. The mean ejection fraction was 0.30 ± 0.09. Twelve patients had overt congestive heart failure. Five had bundle branch block. Before treatment with intravenous amiodarone, the patients had had 6 to 40 episodes of symptomatic VT over 1 to 8 days of hospitalization. All patients received an initial bolus of 5 mg of amiodarone/kg over 15 minutes. Seven patients also received a continuous infusion of 600 to 1,000 mg of amiodarone over 12 to 24 hours. Additional doses depended on the patients' clinical responses. In 11 of 15 patients, antiarrhythmic drugs that had failed to suppress VT were continued during administration of amiodarone.**

**In 12 of 15 patients acute control of VT was obtained with intravenous administration of amiodarone either alone or in combination with previously ineffective drugs. Three patients continued to have frequent episodes of VT while being treated with intravenous amiodarone. Mobitz type I atrioventricular block developed in 1 patient. No patient had high degree atrioventricular block, symptomatic hypotension, or a clinically apparent worsening of congestive heart failure.**

**The use of intravenous amiodarone represents a significant advance in the acute treatment of frequent life-threatening VT refractory to other drugs. With appropriate monitoring, it can be used safely in patients with congestive heart failure, bundle branch block, or acute myocardial infarction.**

Oral amiodarone has been found to be effective in the chronic suppression of recurrent VT.[1–7] However, because its onset of action may be delayed for several days after initiation of treatment, oral amiodarone is not suitable for acute treatment of VT.[8] Reports of use of intravenous amiodarone in the acute treatment of VT have been restricted to reports in the French literature and have involved few patients.[9–12] Our experience with the use of intravenous amiodarone in the treatment of 15 patients with recurrent symptomatic VT refractory to other antiarrhythmic drugs is reported herein.

## Methods

Fifteen patients (Table I) had recurrent symptomatic VT refractory to at least 2 conventional antiarrhythmic drugs administered in doses sufficient to attain therapeutic or supratherapeutic serum levels. These 15 patients were treated with intravenous amiodarone after informed consent was obtained. The mean age of the 11 men and 4 women was 59 ± 11 (SD) years (range 41 to 72). All patients had underlying heart disease. Three patients had left and 2 had right bundle branch block during sinus rhythm. The ejection fraction was measured by radionuclide or contrast angiography in 14 patients; the mean ejection fraction was 0.30 ± 0.09 (range 0.12 to 0.42). Twelve patients had overt congestive heart failure with an $S_3$ gallop and cardiomegaly on chest roentgenogram. Hemodynamic monitoring was performed with a flow-directed thermodilution catheter positioned in the pulmonary artery in 4 patients who had severe heart failure; these patients had a cardiac index of <1.8 liters/min/$m^2$ and a pulmonary capillary wedge pressure >25 mm Hg.

Before treatment with intravenous amiodarone, the patients were hospitalized for 1 to 8 days and had 6 to 40 episodes of symptomatic VT (Table I) documented by electrocardiographic recordings. The rate of VT was 130 to 250 beats/min. In 1 patient (Case 1), the VT was always nonsustained but was associated with symptoms of transient lightheadedness lasting 15 to 60 seconds. One patient (Case 11) had incessant VT with lightheadedness over a 24-hour period before receiving intravenous amiodarone. In the remaining 13 patients, direct-current counter shock was required 2 to 25 times to terminate episodes of VT associated with loss of consciousness or severe hypotension.

* Onset of most recent episodes of VT just before treatment with intravenous amiodarone. † Severe heart failure, with cardiac index <1.8 liters/min/$m^2$ and pulmonary capillary wedge pressure >25 mm Hg.
AMI = acute myocardial infarction; B = bretylium; CCM = congestive cardiomyopathy; D = disopyramide; DDC = direct-current countershock; E = encainide; IHD = ischemic heart disease (chronic); L = lidocaine; PA = procainamide; Pf = propafenone; Pr = propranolol; Q = quinidine.

The antiarrhythmic therapies that failed to suppress VT before administration of intravenous amiodarone are summarized in Table I. The following doses were administered: intravenous lidocaine, a loading dose of 75 to 225 mg followed by a continuous infusion of 2 to 5 mg/min; intravenous procainamide, a loading dose of 600 to 1,000 mg followed by a continuous infusion of 3 to 4 mg/min; intravenous bretylium, a loading dose of 300 to 1,500 mg followed by a continuous infusion of 2 to 4 mg/min; intravenous propranolol, 10 mg; oral procainamide, 6 to 8 g/day; oral quinidine, 1.2 to 1.6 g/day; oral disopyramide, 400 mg/day; oral propafenone, 900 mg/day; and oral encainide, 240 mg/day. Attempts at overdrive suppression with atrial or ventricular pacing in 5 patients were also unsuccessful in controlling VT.

In the absence of preexisting guidelines, a flexible protocol was developed using varying doses of amiodarone to assess its safety and efficacy. All patients received an initial bolus of amiodarone, 5 mg/kg over 15 minutes. Seven patients then received a continuous infusion of 600 to 1,000 mg of amiodarone over 12 to 24 hours. Additional doses depended on the patients' clinical response.

In 11 of 15 patients, antiarrhythmic agents that had already failed to suppress VT were continued during intravenous administration of amiodarone. These medications were continued because in most cases they slowed the rate of the VT. Three patients (Cases 11, 14, and 15) were treated with 800 to 1,200 mg/day of oral amiodarone for 1 to 5 days before receiving the intravenous form. Among the remaining 12 patients, treatment with 800 mg/day of oral amiodarone was initiated within 1 to 2 days after the acute control of VT with the intravenous form. All patients underwent continuous electrocardiographic monitoring during and for at least 3 to 5 days after the administration of intravenous amiodarone.

After discharge from the hospital, patients were seen at intervals of 1 to 3 months by 1 author or the patient's referring physician. Twenty-four hour continuous ambulatory electrocardiographic recordings were obtained every 1 to 3 months.

## Results

After administration of either a single bolus of amiodarone or a bolus followed by a continuous infusion of amiodarone over 12 to 24 hours, the 4 patients who were treated with amiodarone alone had no further episodes of VT (Table II).

In 6 of 11 patients who were treated with intravenous amiodarone in combination with previously ineffective drugs, there was no further VT after administration of a single bolus or a bolus followed by a continuous infusion of amiodarone over 12 to 24 hours. Two patients required additional boluses of amiodarone for control of VT. Patient 8 had 4 episodes of symptomatic VT after administration of 500 mg of intravenous amiodarone over 15 minutes. The next day, an additional bolus of 300 mg of amiodarone was given, and the patient had no further episodes of VT. Patient 9 had no further episodes of sustained VT after receiving a 400 mg bolus of amiodarone over 15 minutes; however, he continued to have 10- to 15-second bursts of nonsustained VT and was treated with an additional 400 mg of intravenous amiodarone 8 hours later. Because of continued short episodes of nonsustained VT, he was treated with 3 additional boluses of 150 mg of amiodarone every 4 hours and subsequently had no further recurrence of VT. Thus, in a total of 12 (80%) of 15 patients who had multiple episodes of symptomatic VT refractory to other antiarrhythmic drugs, acute control of VT was achieved after intravenous administration of amiodarone.

The remaining 3 patients continued to have frequent episodes of symptomatic VT despite being treated with large doses of intravenous amiodarone for several days. Patient 15 received a total of 3.4 g of intravenous amiodarone over 5 days and was treated concurrently with 1,200 mg/day of oral amiodarone and 6 to 8 g/day of oral procainamide; during the 5 days of intravenous amiodarone therapy, he had 38 episodes of symptomatic VT. VT was suppressed only after the sixth day of treatment with high dose oral amiodarone and procainamide. Patients 13 and 14 continued to have frequent episodes of VT despite treatment with intravenous amiodarone in combination with other antiarrhythmic drugs. These patients died from refractory VT. Thus, intravenous amiodarone was ineffective in providing acute control of VT in 20% of patients (3 of 15) who had frequent VT refractory to other antiarrhythmic drugs.

**Cardiovascular effects:** Three patients had asymptomatic sinus slowing from a baseline rate of 70 to 90 beats/min to 48 to 55 beats/min. No symptomatic sinus pauses occurred during or after intravenous administration of amiodarone.

One patient (Case 13) had asymptomatic Mobitz I atrioventricular block 4 hours after intravenous administration of 350 mg of amiodarone. However, no patient had high degree atrioventricular block during or after intravenous administration of amiodarone.

No patient had clinically apparent worsening of congestive heart failure. However, all 4 patients who had severe heart failure were already being treated with a continuous infusion of a sympathomimetic agent (dopamine or dobutamine) before being treated with intravenous amiodarone. In addition, no patient had symptomatic hypotension attributable to intravenous amiodarone.

**Long-term follow-up:** Patient 7 died from refractory cardiogenic shock despite the acute control of VT with intravenous amiodarone. Of the 12 patients who were discharged from the hospital, 10 were treated with amiodarone (400 to 800 mg/day) as the sole antiarrhythmic drug and 2 were treated with amiodarone (800 to 1,200 mg/day) in combination with procainamide (6 to 8 g/day). The mean duration of follow-up was 8.0 ± 4.5 months (range 1 week to 16 months). Patient 3 died suddenly 1 week after discharge from the hospital. No other patient has had a recurrence of symptomatic VT or cardiac arrest. Continuous ambulatory monitoring has revealed occasional 5- to 10-second episodes of asymptomatic VT (rate 125 beats/min) in Patient 15 and occasional 10- to 15-second episodes of asymptomatic accelerated idioventricular rhythm (rate 80 beats/min) in Patient 4.

## Discussion

This study demonstrates that intravenous amiodarone is both safe and effective in the acute control of recurrent symptomatic VT. Despite the fact that many other antiarrhythmic drugs were unsuccessful in suppressing VT, intravenous amiodarone was effective in preventing recurrent VT, either by itself or in combination with previously ineffective drugs, in 80% of the patients in this series. This finding represents a significant advance in the treatment of critically ill patients with recurrent VT.

Previous reports on the use of intravenous amiodarone in the treatment of VT have assessed the efficacy of amiodarone in providing short-term conversion of an episode of sustained VT to sinus rhythm. Benaim and Uzan,[12] Fauchier et al,[9] and Michat et al[10] reported conversion of VT to sinus rhythm with intravenous amiodarone in 6 of 12, 7 of 10, and 3 of 3 patients, respectively. In our series, episodes of VT usually required immediate conversion to sinus rhythm with direct-current countershock because of cardiovascular collapse. The 1 patient in our series (Patient 11) who had continuous stable VT for 24 hours did have conversion to sinus rhythm shortly after administration of intravenous amiodarone. Thus, the efficacy of intravenous amiodarone is demonstrated both by its ability to convert ongoing VT to sinus rhythm and by its prevention of further recurrences of VT in patients who had been having frequent bouts of life-threatening VT.

Among the patients treated with 1 or more boluses of amiodarone, short-term control of VT was obtained in 7 of 8. Among the patients who received a bolus followed by continuous infusion of 600 to 1,000 mg over 12 to 24 hours, VT was suppressed in 5 of 7. However, because of the uncontrolled nature of this study, no conclusion can be drawn regarding the relative efficacy of the bolus technique versus the bolus/constant infusion technique in suppressing VT. No deleterious effects have been observed in patients receiving a larger dose

of amiodarone in the form of a bolus followed by a constant infusion, either by itself or in combination with intravenous lidocaine, procainamide, or bretylium.

All patients in this series had depressed left ventricular function, with an ejection fraction ≤0.4 in 13 of 14 patients in whom it was measured and overt congestive heart failure in 12. Intravenous amiodarone did not result in symptomatic hypotension or a clinically apparent worsening of congestive heart failure in any patient, including the 4 who had acute myocardial infarction. Previous reports have also demonstrated that intravenous amiodarone can be administered safely to patients with acute myocardial infarction or left ventricular failure.[9,13] However, hypotension and cardiovascular collapse have been reported as complications of intravenous amiodarone.[12,14] In our series, patients with severe heart failure were already being treated with dopamine or dobutamine when they received intravenous amiodarone; this may have masked a worsening in hemodynamic status that might otherwise have occurred due to amiodarone therapy. We recommend hemodynamic monitoring whenever possible in patients with severe heart failure who are treated with intravenous amiodarone. Hypotension or an elevation in pulmonary capillary wedge pressure may necessitate treatment with intravenous sympathomimetic or preload-reducing agents, or both.

Although intravenous amiodarone resulted in asymptomatic Mobitz I atrioventricular block in 1 patient, in no patient did it precipitate high degree atrioventricular block, including the 5 patients who had underlying bundle branch block. In the series of Benaim and Uzan,[12] intravenous amiodarone did not precipitate atrioventricular block in 33 patients who had a preexisting bundle branch block. However, 2 cases of infranodal block precipitated by intravenous amiodarone in patients with a preexisting bundle branch block have been reported.[15] Thus, patients should undergo continuous electrocardiographic monitoring when being treated with intravenous amiodarone, especially in the presence of an underlying bundle branch block.

In 3 patients in our series asymptomatic sinus bradycardia developed after administration of intravenous amiodarone; however, none had a symptomatic sinus pause. This is consistent with the series studied by Touboul et al[16] in which sinus nodal function was assessed in 24 patients before and after a bolus of 5 mg/kg of amiodarone. They found a mild decrease in sinus rate in 12 of 24 patients and a mean increase of 110 ms in the sinus nodal recovery time in 17 of 24 patients. No sinus pauses occurred after intravenous administration of amiodarone. However, in our series as well as in the report by Touboul et al, no patient had symptomatic sinus nodal disease. Thus, the safety of intravenous amiodarone in patients with symptomatic sinus nodal dysfunction remains to be determined.

Our study had 2 limitations. In the majority of patients, treatment was continued with 1 or more other antiarrhythmic drug administered concurrently with intravenous amiodarone. Thus, although these other agents had failed to control VT by themselves, an additive effect of intravenous amiodarone cannot be ruled out. Second, all patients in whom VT was controlled acutely with intravenous amiodarone began treatment with daily oral amiodarone shortly thereafter. Therefore, no conclusion can be drawn regarding the duration of effect of intravenous amiodarone in suppressing VT.

# Dobutamine/Dobutrex®

Dobutamine HCl

**Description:** Dobutrex is (±)-4-[2-[[3-(*p*-hydroxyphenyl)-1-methylpropyl] amino]ethyl]-pyrocatechol hydrochloride. It is a synthetic catecholamine.

Molecular Formula: $C_{18}H_{23}NO_3 \cdot HCl$ Molecular Weight: 337.84

The clinical formulation is supplied in a sterile lyophilized form for intravenous use only. Each vial contains 250 mg of dobutamine and 250 mg of mannitol. Hydrochloric acid is used to adjust the *p*H. The *p*H of the reconstituted solution is between 2.5 and 5.5.

**Clinical Pharmacology:** Dobutrex is a direct-acting inotropic agent whose primary activity results from stimulation of the beta receptors of the heart while producing comparatively mild chronotropic, hypertensive, arrhythmogenic, and vasodilative effects. It does not cause the release of endogenous norepinephrine, as does dopamine. In animal studies, dobutamine produces less increase in heart rate and less decrease in peripheral vascular resistance for a given inotropic effect than does isoproterenol.

In patients with depressed cardiac function, both dobutamine and isoproterenol increase the cardiac output to a similar degree. In the case of dobutamine, this increase is usually not accompanied by marked increases in heart rate (although tachycardia is occasionally observed), and the cardiac stroke volume is usually increased. In contrast, isoproterenol increases the cardiac index primarily by increasing the heart rate while stroke volume changes little or declines.

Facilitation of atrioventricular conduction has been observed in human electrophysiologic studies and in patients with atrial fibrillation.

Systemic vascular resistance is usually decreased with administration of dobutamine. Occasionally, minimum vasoconstriction has been observed.

Most clinical experience with dobutamine is short-term—up to several hours in duration. In the limited number of patients who were studied for 24, 48, and 72 hours, a persistent increase in cardiac output occurred in some, whereas the output of others returned toward base-line values.

The onset of action of Dobutrex is within one to two minutes; however, as much as ten minutes may be required to obtain the peak effect of a particular infusion rate.

The plasma half-life of dobutamine in humans is two minutes. The principal routes of metabolism are methylation of the catechol and conjugation. In human urine, the major excretion products are the conjugates of dobutamine and 3-O-methyl dobutamine. The 3-O-methyl derivative of dobutamine is inactive.

Alteration of synaptic concentrations of catecholamines with either reserpine or tricyclic antidepressants does not alter the actions of dobutamine in animals, which indicates that the actions of dobutamine are not dependent on presynaptic mechanisms.

**Indications and Usage:** Dobutrex is indicated when parenteral therapy is necessary for inotropic support in the short-term treatment of adults with cardiac decompensation due to depressed contractility resulting either from organic heart disease or from cardiac surgical procedures.

In patients who have atrial fibrillation with rapid ventricular response, a digitalis preparation should be used prior to institution of therapy with Dobutrex.

**Contraindication:** Dobutrex is contraindicated in patients with idiopathic hypertrophic subaortic stenosis.

**Warnings:** 1. *Increase in Heart Rate or Blood Pressure*—Dobutrex may cause a marked increase in heart rate or blood pressure, especially systolic pressure. Approximately 10 percent of patients in clinical studies have had rate increases of 30 beats/minute or more, and about 7.5 percent have had a 50-mm Hg or greater increase in systolic pressure. Reduction of dosage usually reverses these effects promptly. Because dobutamine facilitates atrioventricular conduction, patients with atrial fibrillation are at risk of developing rapid ventricular response. Patients with preexisting hypertension appear to face an increased risk of developing an exaggerated pressor response.

2. *Ectopic Activity*—Dobutrex may precipitate or exacerbate ventricular ectopic activity, but it rarely has caused ventricular tachycardia.

**Precautions: 1. During the administration of Dobutrex, as with any adrenergic agent, ECG and blood pressure should be continuously monitored. In addition, pulmonary wedge pressure and cardiac output should be monitored whenever possible to aid in the safe and effective infusion of Dobutrex.**

2. Hypovolemia should be corrected with suitable volume expanders before treatment with Dobutrex is instituted.

3. Animal studies indicate that Dobutrex may be ineffective if the patient has recently received a beta-blocking drug. In such a case, the peripheral vascular resistance may increase.

4. No improvement may be observed in the presence of marked mechanical obstruction, such as severe valvular aortic stenosis.

*Usage Following Acute Myocardial Infarction*—Clinical experience with Dobutrex following myocardial infarction has been insufficient to establish the safety of the drug for this use. There is concern that any agent which increases contractile force and heart rate may increase the size of an infarction by intensifying ischemia, but it is not known whether dobutamine does so.

*Usage in Pregnancy*—Reproduction studies performed in rats and rabbits have revealed no evidence of impaired fertility, harm to the fetus, or teratogenic effects due to dobutamine. However, the drug has not been administered to pregnant women and should be used only when the expected benefits clearly outweigh the potential risks to the fetus.

*Pediatric Use*—The safety and effectiveness of Dobutrex for use in children have not been studied.

*Drug Interactions*—There was no evidence of drug interactions in clinical studies in which Dobutrex was administered concurrently with other drugs, including digitalis preparations, furosemide, spironolactone, lidocaine, glyceryl trinitrate, isosorbide dinitrate, morphine, atropine, heparin, protamine, potassium chloride, folic acid, and acetaminophen. Preliminary studies indicate that the concomitant use of dobutamine and nitroprusside results in a higher cardiac output and, usually, a lower pulmonary wedge pressure than when either drug is used alone.

**Adverse Reactions:** *Increased Heart Rate, Blood Pressure, and Ventricular Ectopic Activity*—A 10 to 20-mm increase in systolic blood pressure and an increase in heart rate of five to 15 beats per minute have been noted in most patients. (See Warnings regarding exaggerated chronotropic and pressor effects.) Approximately 5 percent of patients have had increased premature ventricular beats during infusions. These effects are dose related.

*Miscellaneous Uncommon Effects*—The following adverse effects have been reported in 1 to 3 percent of patients: nausea, headache, anginal pain, nonspecific chest pain, palpitations, and shortness of breath.

No abnormal laboratory values attributable to Dobutrex have been observed.

*Longer-Term Safety*—Infusions of up to 72 hours have revealed no adverse effects other than those seen with shorter infusions.

**Overdosage:** In case of overdosage, as evidenced by excessive alteration of blood pressure or by tachycardia, reduce the rate of administration or temporarily discontinue Dobutrex until the patient's condition stabilizes. Because the duration of action of Dobutrex is short, usually no additional remedial measures are necessary.

**Administration and Dosage:** *Reconstitution and Stability*—Dobutrex is incompatible with alkaline solutions and should not be mixed with products such as 5% Sodium Bicarbonate Injection.

Dobutrex may be reconstituted with Sterile Water for Injection or 5% Dextrose Injection. To reconstitute, add 10 ml of diluent to Vial No. 7051, Dobutrex, 250 mg. If the material is not completely dissolved, add another 10 ml of diluent. The reconstituted solution may be stored under refrigeration for 48 hours or at room temperature for six hours.

Reconstituted Dobutrex must be further diluted to at least 50 ml prior to administration in 5% Dextrose Injection, 0.9% Sodium Chloride Injection, or Sodium Lactate Injection. Intravenous solutions should be used within 24 hours.

Solutions containing Dobutrex may exhibit a color that, if present, will increase with time. This color change is due to slight oxidation of the drug, but there is no significant loss of potency during the reconstitution time periods stated above.

*Recommended Dosage*—The rate of infusion needed to increase cardiac output usually ranges from 2.5 to 10 mcg/kg/min (see table). On rare occasions, infusion rates up to 40 mcg/kg/min have been required to obtain the desired effect.

Rates of Infusion for Concentrations of 250, 500, and 1000 mcg/ml

*250 mg per liter of diluent
†500 mg per liter or 250 mg per 500 ml of diluent
‡1000 mg per liter or 250 mg per 250 ml of diluent

The rate of administration and the duration of therapy should be adjusted according to the patient's response, as determined by heart rate, presence of ectopic activity, blood pressure, urine flow, and, whenever possible, measurement of central venous or pulmonary wedge pressure and cardiac output.

Concentrations up to 5000 mcg/ml have been administered to humans (250 mg/50 ml). The final volume administered should be determined by the fluid requirements of the patient.

**How Supplied:** Vials Dobutrex® (dobutamine hydrochloride, Lilly), for Injection (lyophilized), equivalent to 250 mg dobutamine, 20-ml size, rubber-stoppered, in packages of 1. (121979)

DIASONICS CARDIO/IMAGING

# *Advancing*

## *Phased Array Ultrasound for the Advancing Cardiologist*

**—Major technology advancement now available in the 3400R.**

Rapid change in cardiac ultrasound has brought confusion, growth and uncertainty over the last six years. Technological change is continuing to bring innovation and improvements in image quality, image processing, digital M-mode, doppler and quantitation.

Diasonics Cardio/Imaging (formerly Varian Ultrasound) is proud to introduce a major new development...a development which brings order to change and an end to uncertainty...a new concept in phased array ultrasound: **System Modularity.**

This computer based modular phased array system and its unique modules bring to new and existing 3400R customers the ability to both purchase and to maintain a state-of-the-art system...a system that does not grow obsolete.

Diasonics Cardio/Imaging's 3400R is the proven leader in 2-D echocardiography, and has a long history of success...success that is worthy of the advancing cardiologist. The 3400R, an imaging system...

*It's Where Imaging Is Going...*

# CLASSIFIED

## CHAIRPERSON

### DEPARTMENT OF THORACIC-CARDIOVASCULAR SURGERY

Nassau Hospital, a 533-bed teaching hospital of SUNY at Stony Brook is seeking outstanding candidates to chair its cardio-thoracic department. Applicants should have demonstrated clinical, teaching and administrative skills as well as proven research productivity. Senior academic rank preferred (Professor or Associate Professor of Surgery). The department conducts a fully approved open heart program and a large volume of thoracic and vascular surgery is performed. There are hospital-supported fellowship positions and an opportunity for research activities. Send CV to John F. Aloia, M.D., Professor of Medicine, Chairman, Search Committee.

**NASSAU HOSPITAL**
259 FIRST STREET
MINEOLA, LONG ISLAND, NEW YORK 11501
*An Equal Opportunity Employer M/F*

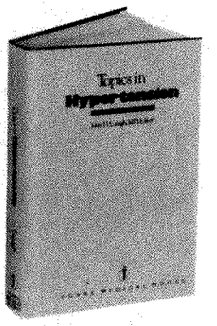
---

**HOUSTON**—POSITION AVAILABLE FOR BOARD CERTIFIED OR ELIGIBLE CARDIOLOGIST. Accredited 67-physician internal medicine group. For further information, send Curriculum Vitae to Administrator, Diagnostic Clinic of Houston, 6448 Fannin, Houston, Texas 77030.

---

### ATTENDING PEDIATRIC CARDIOLOGIST

Assistant Professor of Pediatrics, University of Illinois Hospital Chicago. MD degree certified or eligible in Pediatrics, completing or completed fellowship pediatric cardiology. Duties include cardiac catherization, patient care, teaching and research. Contact Elizabeth Fisher, M.D., Professor, Clinical Pediatrics, Director Pediatric Cardiology, 840 South Wood, Room 1205 HA, Chicago, IL 60612. The University of Illinois is an affirmative action equal opportunity employer.



---

PROFESSIONAL RESUME SERVICES, 1125 SOUTH CEDAR CREST BOULEVARD, ALLENTOWN, PENNSYLVANIA 18103. CV PREPARATION FOR PHYSICIANS. PROMPT. CONFIDENTIAL. CALL OR WRITE FOR INFORMATION. (215) 433-4112.

---

*Laragh's eagerly awaited new book on the silent killer*

## TOPICS IN HYPERTENSION

Edited by
**John H. Laragh, MD**
*Master Professor of Medicine*
*Director, The Cardiovascular Center Chief, Cardiology Division The New York Hospital-Cornell Medical Center*

**644 pages. 36 chapters by 85 internationally known specialists. Illustrated. Comprehensively indexed. $49.00. Available on 30-day approval.**

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice...and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

This book is conveniently organized for effective consultation and reading:

- **Section 1** considers recently maturing biochemical and pathophysiologic aspects of the problem.
- **Section 2** deals with new physiologic approaches to diagnosis.
- **Section 3** discusses new perceptions of the clinical and prognostic aspects of hypertension.
- **Section 4** considers in detail the more recently introduced modes of therapy. These new agents presage the beginning of a new era of more selective and specific therapy for increasing numbers of patients.

**YORKE MEDICAL BOOKS** AJCA3
Box C-757, Brooklyn, New York 11205

Send me, on approval, _____ copies of Laragh's TOPICS IN HYPERTENSION at $49.00. I will consult and read this new manual for 30 days, then remit only if I consider it a necessary addition to my library. Otherwise I will return it without further obligation.

☐ Send bill, plus shipping cost.
☐ Payment herewith. Publisher pays shipping. Same return privilege.
☐ Charge my ☐ MasterCard ☐ Visa
☐ Card No. _____ Exp. date _____

*Please add Sales Tax in N.Y. State. Outside Western Hemisphere price is $57.00 and prepayment or credit card number is required. Thank you.*

DIASONICS CARDIO/IMAGING

# *Innovative*

## *Mechanical Sector Scanner for the Innovative Cardiologist*

An Innovation is the introduction of something new. The combination of intelligent thought creatively applied with advanced technology produces positive change. You provide the first element of that equation and Diasonics Cardio/Imaging (formerly Varian Ultrasound) provides the second.

Designed around a powerful main frame computer, the CardioVue 100 is the most technologically advanced mechanical sector scanner available today. Designed to meet the imaging requirements of the most demanding cardiologist, the CardioVue 100 is the only mechanical sector imaging system of modular design that offers both simultaneous real-time M-mode and steerable simultaneous pulsed and continuous wave doppler. Compact, lightweight, and easy to use, the CardioVue 100 has been designed to succeed in meeting a wide variety of applications including cardiac small parts, peripheral vascular and neonatal imaging.

Diasonics has built its reputation on delivering the best images in real-time ultrasound, and we further enhance that reputation with the CardioVue 100.

Clearly, the CardioVue 100 imaging system is an innovation that anticipates the future of cardiology...

*It's Where Imaging Is Going...*

I'd like to know more about:

- ☐ 3400R Phased Array Systems
- ☐ CardioVue 100 Mechanical Sector Systems
- ☐ Cardio ReVue Center

**ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066**

## What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

## CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

***"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."*** Philip Reichert, M.D. New York State Journal of Medicine, September, 1981

***"...recommend...to any reader interested in the literature of cardiology."*** Irwin R. Callen, M.D. JAMA, November, 1981

**SPECIAL DISCOUNT OFFER**

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

☐ **YES,** please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

**Yorke Medical Books,** Box C-757, Brooklyn, NY 11205 AJCA3

☐ Please send me a copy of the 1982 edition at the full price of $45.00. I do not wish to place a standing order.

## Works one night at a time... from the first night.

# RESTORIL®

C IV

15 mg
30 mg
capsules

(temazepam)

## Hypnotic action with insignificant accumulation

Please turn page for prescribing information.

## RESTORIL® (temazepam) C-IV capsules

One 30-mg capsule, h.s.—*usual adult dosage.*
One 15-mg capsule, h.s.—*recommended initial dosage for elderly and/or debilitated patients.*

**INDICATIONS AND USAGE:** Restoril® (temazepam) is indicated for the relief of insomnia associated with complaints of difficulty in falling asleep, frequent nocturnal awakenings, and/or early morning awakenings. Since insomnia is often transient and intermittent, the prolonged administration of Restoril is generally not necessary or recommended. Restoril has been employed for sleep maintenance for up to 35 consecutive nights of drug administration in sleep laboratory studies.

The possibility that the insomnia may be related to a condition for which there is more specific treatment, should be considered.

**CONTRAINDICATIONS:** Benzodiazepines may cause fetal damage when administered during pregnancy. An increased risk of congenital malformations associated with the use of diazepam and chlordiazepoxide during the first trimester of pregnancy has been suggested in several studies. Also, ingestion of therapeutic doses of benzodiazepine hypnotics during the last weeks of pregnancy has resulted in neonatal CNS depression. Restoril is contraindicated in pregnant women. Consider a possibility of pregnancy when instituting therapy or whether patient intends to become pregnant.

**WARNINGS:** Patients receiving Restoril (temazepam) should be cautioned about possible combined effects with alcohol and other CNS depressants.

**PRECAUTIONS:** In elderly and/or debilitated patients, it is recommended that initial dosage be limited to 15 mg. The usual precautions are indicated for severely depressed patients or those in whom there is any evidence of latent depression; it should be recognized that suicidal tendencies may be present and protective measures may be necessary.

If Restoril is to be combined with other drugs having known hypnotic properties or CNS-depressant effects, due consideration should be given to potential additive effects.

*Information for Patients:* Patients receiving Restoril should be cautioned about possible combined effects with alcohol and other CNS depressants. Patients should be cautioned not to operate machinery or drive a motor vehicle. They should be advised of the possibility of disturbed nocturnal sleep for the first or second night after discontinuing the drug.

*Laboratory Tests:* The usual precautions should be observed in patients with impaired renal or hepatic function. Abnormal liver function tests as well as blood dyscrasias have been reported with benzodiazepines.

*Pregnancy:* Pregnancy Category X. See Contraindications.

*Pediatric Use:* Safety and effectiveness in children below the age of 18 years have not been established.

**ADVERSE REACTIONS:** The most common adverse reactions were drowsiness, dizziness and lethargy. Other side effects include confusion, euphoria and relaxed feeling. Less commonly reported were weakness, anorexia and diarrhea. Rarely reported were tremor, ataxia, lack of concentration, loss of equilibrium, falling and palpitations. And rarely reported were hallucinations, horizontal nystagmus and paradoxical reactions, including excitement, stimulation and hyperactivity.

Restoril is a controlled substance in Schedule IV. Caution must be exercised in addiction-prone individuals or those who might increase dosage.

**DOSAGE AND ADMINISTRATION:** *Adults:* 30 mg usual dosage before retiring; 15 mg may suffice in some. *Elderly and/or debilitated:* 15 mg recommended initially until individual response is determined.

**SUPPLIED:** Restoril (temazepam) capsules—15 mg maroon and pink, imprinted "RESTORIL 15 mg"; 30 mg, maroon and blue, imprinted "RESTORIL 30 mg". Packages of 100, 500 and ControlPak® packages of 25 capsules (continuous reverse-numbered roll of sealed blisters). SDZ1-159

*Before prescribing, see package insert for full product information.*

## INFECTIONS
### IN THE ABNORMAL HOST

**Edited by Michael H. Grieco, M.D.**
**Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color**

**Infections in the Abnormal Host** discusses in 36 revealing chapters the mechanics of host defenses . . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

Consultation and study of **Infections** will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

**Check this list of chapters**

**PART I HOST DEFENSES**

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

**PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST**

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

**PART III MANAGEMENT**

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy • Index

# Alterations in Left Ventricular Filling With Beta-Adrenergic Blockade

FETNAT M. FOUAD, MD, MAREK J. SLOMINSKI, MD, ROBERT C. TARAZI, MD, and JOE H. GALLAGHER, PhD

**Cardiac effects of beta-adrenergic blocking drugs represent a balance between depression of myocardial function and relief of pressure load. To determine the relative importance of each, cardiac and hemodynamic indexes were measured by radioisotope technique (technetium-99m–human serum albumin) in 21 patients treated with either metoprolol (n = 8) or nadolol (n = 13) for 1 month. No significant difference was found between the 2 groups, and the results were pooled. Cardiac output was significantly ($p < 0.01$) and equally reduced in responders and nonresponders (−0.96 versus −1.33 liters/min, difference not significant [NS]), and ejection fraction was not altered significantly in either. The main changes with treatment were observed in the left ventricular volume curves; responders maintained the same ejection velocity despite beta blockade and had a more rapid early ventricular filling rate ($p < 0.05$). In contrast, nonresponders had a reduced velocity of ejection ($p < 0.01$) and a slower rate of ventricular filling ($p < 0.01$), suggesting either altered relaxation rate or decreased left ventricular compliance. Thus, beta-adrenergic blockade can significantly alter ventricular diastolic function, but these effects are overshadowed by blood pressure reduction in responders.**

Most studies of the cardiac effects of beta-adrenergic blocking agents have dealt with their effects on the systolic phase of the cardiac cycle; these were assessed by measurements of cardiac output,[1–3] the first derivative of left ventricular pressure (dP/dt),[4] or ejection fraction.[5,6] However, the diastolic part of the cardiac cycle was recently shown to be an important determinant of cardiac function.[7] Adrenergic factors have been found to influence this phase markedly by their effect on ventricular relaxation.[8] We therefore analyzed the effect of beta-adrenergic blockade on diastolic filling of the heart in hypertensive patients. All were given only a beta-blocking agent, and patients with good blood pressure response were compared with those whose blood pressure was not changed in order to evaluate the relative importance of both variables: reduction of afterload, and cardiac effects of beta-adrenergic blockade.

From the Research Division, The Cleveland Clinical Foundation, Cleveland, Ohio. This study was supported in part by grants from the National Institutes of Health, Bethesda, Maryland, Whitaker Foundation, Boston, Massachusetts, and the American Heart Association-Northeast Ohio, Cleveland, Ohio. Manuscript received May 11, 1982; revised manuscript received July 27, 1982, accepted July 30, 1982.

Address for reprints: Fetnat M. Fouad, MD, Research Division, Cleveland Clinic, Cleveland, Ohio 44106.

## Methods

The study included 21 patients with essential hypertension (4 women and 17 men) who freely consented to this investigation, which was explained to them in detail. All gave informed consent both to the drug used and to the tests required. All patients were either untreated or had discontinued previous medications (including vasodilators, methyldopa, beta-blocking agents, and diuretics, alone or in combination) for at least 3 weeks. In all, the diagnosis was established by careful examination or by tests for possible causes of secondary hypertension and evaluation of target organ involvement, as described in detail previously.[9] Their ages ranged from 19 to 55 years. Only 1 had history of coronary artery disease; he had previously undergone coronary bypass surgery but had no symptoms postoperatively, no signs of myocardial infarction, and no evidence of left ventricular dyskinesia. Three patients had electrocardiographic signs of left ventricular hypertrophy.

**Protocol:** Patients were studied before and after 1 month of beta-blockade therapy. All tests were done in the morning after an overnight fast and 30 minutes' supine rest. Each test included measurement of blood pressure (sphygmomanometer cuff) heart rate (lead II electrocardiogram), total blood volume[9] (RISA), cardiac output[10,11] (radionuclide technique), and ejection fraction[12] (gated blood pool technique). After these tests, therapy was started with either the noncardioselective beta-blocking agent nadolol (n = 13) or the relatively cardioselective agent metoprolol (n = 8) in standard doses. All tests were repeated after 4 weeks of treatment.

**Hemodynamic study:** Cardiac output and mean transit time were obtained in duplicate from the first-pass radionuclide study using technetium-99m–human serum albumin (4 and 8 mCi, respectively). Details of the method and its validation were previously reported.[10,11,13] Derived data were calculated from these measurements and from simultaneous blood pressure and heart rate values using standard formulas. Thus, mean arterial pressure, total peripheral resistance, cardiac index, stroke volume, and cardiopulmonary volume were obtained.

Left ventricular volume curves and ejection fraction were obtained by imaging (gated blood pool technique) during the equilibrium phase after the first-pass study, making use of the same circulating radioisotope. The left ventricular volume curve was then analyzed (PDP-15 system) to measure ejection fraction, maximal rates of left ventricular ejection (negative dV/dt), and filling (positive dV/dt) as explained previously in detail.[14]

*Analysis of left ventricular volume curves:* Left ventricular ejection fraction was calculated as follows: left ventricular end-diastolic counts − left ventricular end-systolic counts/left ventricular end-diastolic counts.

For rates of ejection and filling (Fig. 1), Fourier analysis was applied to fit a curve to the data points (16 in our system) by the method of least squares; the time derivative of the curve was computed with use of the Fourier transform technique as a global estimate of the tangent to the curve at each data point. Since this curve represents the radioactivity counts as a mathematical function of time, the derivatives were expressed in counts per second. The negative derivatives corresponded to the decrease in counts or ejection phase, and the positive derivatives corresponded to the increase in counts or filling phase. In this analysis we looked at the largest negative and maximal positive derivatives. These derivatives were sealed by the maximal absolute counts equivalent to the end-diastolic counts to compensate for variation in injected dose and efficiency of the acquisition system. In this way it was possible to compare data from different patients. The units of these new variables were therefore expressed in units of fractional change per second or hertz. Since these variables are proportional to the change in volume per unit time, they have been termed dV/dt.

The filling phase was further analyzed (Fig. 2) to measure the fast filling fraction (FF) and the slow filling fraction (SF) by a modification of the index described by Reduto et al[15]: FF = (ffc − ESc)/ffc = fast filling fraction and SF = (EDs − ffc)/EDc = slow filling fraction, where ffc is the junction between the fast filling and the slow filling phases, ESc = end-systolic counts, and EDc = end-diastolic counts.

**Statistical analysis:** Calculations of averages, paired and unpaired *t* tests, correlation coefficients, and statistical significance of results were performed by standard methods.[16] Values reported are mean ± standard deviation of the mean. Differences were considered statistically significant when $p < 0.05$.

## Results

**Pretreatment hemodynamic characteristics:** The hemodynamic pattern showed a wide spectrum of variations. Cardiac output ranged from 3.5 to 7.8 liters/min (normal for the laboratory 3.8 to 7.6 liters/min), heart rate ranged from 49 to 100 beats/min, and blood pressure varied from 89 to 145 mm Hg. Ejection fraction was normal in all (46 to 73%, normal for the laboratory 46 to 73%) except 3 patients, in whom it was 43 to 44%.

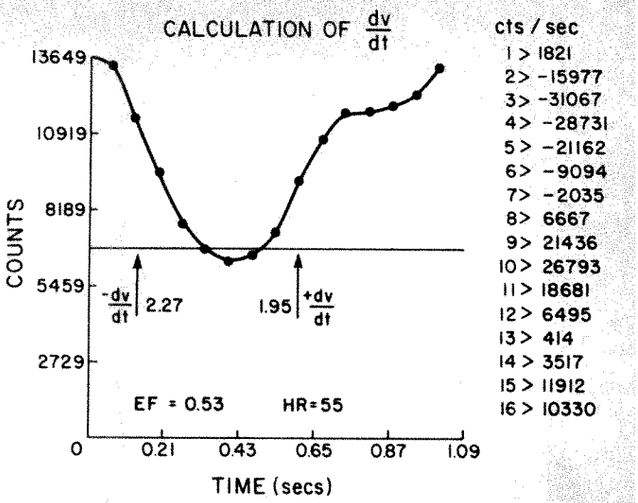

**FIGURE 1.** Left ventricular volume curve (technetium-99m–human serum albumin, gated blood pool technique) in a normal volunteer illustrating the calculation of positive and negative dV/dt. The counts per second (cts/sec) indicate the derivatives at each of the 16 data points on the curves (Fourier analysis) before normalization for end-diastolic counts. EF = ejection fraction; HR = heart rate.

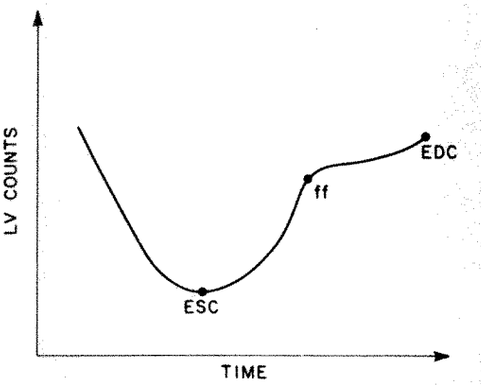

**FIGURE 2.** Left ventricular (LV) volume curve: schematic illustration of FF and SF fractions. See text for details. EDC = end-diastolic counts; ESC = end-systolic counts; ff = counts at end of fast filling phase.

**TABLE I Hemodynamic Changes During Beta-Blockade Therapy in Responders**

| | Metoprolol (n = 5) | | Nadolol (n = 7) | |
|---|---|---|---|---|
| | Control | 1 Month | Control | 1 Month |
| HR (beats/min) | 75 ± 4 | 58 ± 7* | 74 ± 12 | 57 ± 8* |
| MAP (mm Hg) | 121 ± 21 | 102 ± 18* | 115 ± 14 | 97 ± 6* |
| CO (liters/min) | 5.6 ± 1.7 | 4.8 ± 1.0* | 5.3 ± 1.0 | 4.2 ± 0.7* |
| SV (ml) | 74 ± 22 | 82 ± 14 | 72 ± 10 | 74 ± 8 |
| TPR (units·m$^2$) | 43 ± 20 | 45 ± 14 | 44 ± 13 | 46 ± 6 |
| MTT (s) | 8.4 ± 1.1 | 9.8 ± 1.9† | 8.6 ± 1.8 | 9.7 ± 1.1† |
| EF (%) | 52 ± 6 | 52 ± 7 | 48 ± 8 | 53 ± 6 |
| −dV/dt (Hz) | 2.6 ± 0.5 | 2.3 ± 0.5 | 2.5 ± 0.5 | 2.4 ± 0.4 |
| +dV/dt (Hz) | 2.4 ± 0.5 | 2.7 ± 0.2 | 2.3 ± 0.7 | 2.1 ± 0.5 |

* $p < 0.01$; † $p < 0.05$.

Values are means ± standard deviation. Differences in response to beta blockade with the 2 drugs were not statistically significant. CO = cardiac output; EF = ejection fraction; HR = heart rate; MAP = mean arterial pressure; MTT = mean transit time; SV = stroke volume; TPR = total peripheral resistance.

**TABLE II Hemodynamic Changes During Beta-Blockade Therapy in Nonresponders**

| | Metoprolol (n = 3) | | Nadolol (n = 6) | |
|---|---|---|---|---|
| | Control | 1 Month | Control | 1 Month |
| HR (beats/min) | 70 ± 27 | 58 ± 14* | 84 ± 9 | 59 ± 6* |
| MAP (mm Hg) | 117 ± 24 | 120 ± 30 | 122 ± 14 | 119 ± 18 |
| CO (liters/min) | 4.9 ± 1.3 | 3.7 ± 1.1* | 5.9 ± 1.4 | 4.5 ± 0.8* |
| SV (ml) | 73 ± 15 | 63 ± 8 | 70 ± 13 | 76 ± 14 |
| TPR (units·m$^2$) | 42 ± 15 | 58 ± 23* | 45 ± 11 | 54 ± 13* |
| MTT (s) | 9.0 ± 2.6 | 10.7 ± 2.5† | 7.7 ± 1.4 | 9.8 ± 2.1† |
| EF (%) | 58 ± 15 | 47 ± 7 | 49 ± 9 | 48 ± 10 |
| −dV/dt (Hz) | 2.5 ± 0.1 | 2.3 ± 0.2* | 2.8 ± 0.3 | 2.2 ± 0.4* |

| SF | 0.17 ± 0.05 | 0.20 ± 0.08 | NS |

Values are means ± standard deviation. FF = fast filling fraction; SF = slow filling fraction; other abbreviations as before.

After 1 month of therapy, 12 patients (responders) had a decrease in blood pressure to <140/90 mm Hg (7 with nadolol and 5 with metoprolol); the others (9 patients) showed little or no response and were considered nonresponders. The hemodynamic characteristics of response were as previously described in 2 larger series.[6,12] With either drug, heart rate and cardiac output decreased and mean transit time was prolonged in both responders and nonresponders. Total peripheral resistance increased in the nonresponders but remained unchanged despite the decrease in output in responders. Moreover, in both responders and nonresponders, the initial heart rate correlated significantly with the slowing of heart rate during treatment ($r = -0.65$ and $-0.85$, respectively, $p < 0.01$ for both), and the initial cardiac output correlated with reduction of cardiac output during treatment ($r = -0.76$ and $-0.68$, respectively, $p < 0.05$ for both).

Comparison of responses to nadolol and metoprolol showed no statistically significant differences in hemodynamic changes induced by treatment, either in responders (Table I) or in nonresponders (Table II). The results with both beta-blocking agents were therefore pooled (Tables III and IV). The 2 groups had similar reduction in heart rate (75 ± 9 to 58 ± 7 beats/min in responders and 79 ± 16 to 58 ± 9 beats/min in nonresponders, $p < 0.01$ for both). The effect of beta blockade on left ventricular ejection and filling rates was evaluated from the changes recorded in negative and positive dV/dt and in the fast and slow filling fractions (positive dV/dt, FF and SF, Table V). Responders showed no significant change in the rate of ejection, while nonresponders had significant slowing of negative dV/dt. Left ventricular filling was also altered differently in responders and nonresponders. In responders, the velocity of filling in early diastole (fast filling fraction, FF) was increased. There was, therefore, a longer period of diastasis because of both the slower heart rate and the increased FF; this possibly accounted for the slower rate of filling found in the latter part of diastole (slow filling phase, SF). In nonresponders, on the other hand, peak left ventricular filling rate (positive dV/dt) and FF slowed during treatment while changes in SF were not significant.

## Discussion

A significant difference was found in the effect of beta blockade on left ventricular filling rate in patients whose blood pressure was reduced by treatment and those who showed no appreciable blood pressure response. Effective beta blockade was manifested in both groups by slowing of heart rate, reduction in cardiac output, and prolongation of mean transit time (Tables III and IV); the changes in both groups were statistically significant from control values but not statistically different from each other. As in our previous experience, total peripheral resistance did not change significantly in those whose blood pressure decreased while it increased in those with no blood pressure reduction[6,17]; this applied to both metoprolol and nadolol (Tables I and II).

The cardiac effects of beta blockade were more subtle than systemic hemodynamic effects, and their charac-

teristics were markedly influenced by the behavior of the arterial pressure. Thus, peak left ventricular ejection rate (negative dV/dt) was reduced by beta blockade when blood pressure was unchanged (nonresponders). On the other hand, negative dV/dt was not significantly changed despite the beta-adrenergic blockade when pressure was reduced, possibly because this reduction counterbalanced the negative inotropic effect of the blockade. Similar changes were seen in ventricular filling; peak left ventricular filling rate (positive dV/dt) speeded up in responders but slowed in nonresponders. This was associated with a reduction in SF in responders, probably because of the prolonged diastasis, whereas changes in SF were not significant in nonresponders. Thus, the effects of beta blockade on left ventricular filling were more apparent when not counterbalanced by a reduction in pressure load. Filling fraction in late diastole (SF) was altered in opposite direction to the rapid filling phase; it was slowed when rapid filling rate and fraction increased and was slightly increased when rapid filling was slowed.

Since no factor other than blood pressure differed significantly in responders and nonresponders, one may conclude that the slowing of ejection rate and FF in nonresponders represents the effects of beta blockade on cardiac dynamics. Beta blockade was reported to influence the hypertrophic response of the heart[18,19] and blood vessels[19] to hypertension. It might be tempting to speculate whether the improvement in rapid filling could be related to myocardial compositional changes. However, the time period involved, as well as the duration of hypertension in our patients, made this hypothesis unlikely. More relevant is the reported observation of adrenergic influences on left ventricular relaxation. It has been postulated that sympathetic stimulation increases the rate of relaxation[8]; to the extent that the rate of relaxation can influence the rate of filling,[20] it is possible that beta blockers might lead to slower filling of the left ventricle because of slower relaxation.

The hemodynamic consequences of a slower left ventricular filling might be important. Guazzi et al[21] reported that patients who had no blood pressure response to beta blockade had an increase in pulmonary wedge pressure, whereas those with a decrease in blood pressure and total peripheral resistance showed a decrease in pulmonary wedge pressure. These observations appear to agree with our findings of slowed left ventricular filling rate in nonresponders.

Finally, one may wonder whether the slower filling rate might not itself influence the adaptation of total peripheral resistance to the reduction in cardiac output during beta-blockade therapy. There are no data to support this hypothesis, but it does agree with some of the theories advanced[22] to explain the antihypertensive effects of beta-adrenergic blocking agents. Future studies to determine simultaneously left ventricular pressure and volume changes might add to our understanding of the effects of beta-blocking agents on cardiac function.

# Intravascular Volume, Extracellular Fluid Volume, and Total Body Water in Obese and Nonobese Hypertensive Patients

JOCELYNE RAISON, MD, APOSTOLOS ACHIMASTOS, MD, JEAN BOUTHIER, MD, GERARD LONDON, MD, and MICHEL SAFAR, MD

**Intraarterial blood pressure, plasma volume, extracellular and interstitial (IFV) fluid volumes, and total and intracellular (IBW) body water were evaluated in 50 men: 16 obese hypertensive patients, 16 nonobese hypertensive patients, and 18 normal subjects of similar age. In obese hypertensive subjects, the IBW/IFV ratio was significantly increased ($p < 0.01$) in comparison with both control subjects and nonobese hypertensive patients. After body weight reduction, blood pressure ($p < 0.01$), heart rate ($p < 0.05$), and the IBW/IFV ratio ($p < 0.01$) significantly decreased. The decrease in the ratio was due to an absolute increase in interstitial fluid volume, related to a shift of fluid volume from the intracellular to the interstitial space. Thus, obese hypertensive patients have an increased water cell content, causing an altered partition between the intracellular and the interstitial spaces.**

In obese hypertensive patients, a reduction of body weight appears to lower arterial blood pressure.[1] However, the underlying mechanisms are still poorly understood. Some observations suggest that the decrease in sodium intake that is concomitant with weight loss is the major factor contributing to a decrease in blood pressure.[2] On the other hand, Reisin et al[3] have shown that subjects who were losing weight had lower blood pressure than did control subjects, despite nearly equivalent, uncontrolled high sodium intake in both groups. However, in all these studies, the effects of sodium intake and body weight reduction on blood pressure were considered as being independent of each other. This interpretation is surprising since the changes in sodium intake and body weight may have independent direct effects on fluid volumes, thus modifying the blood pressure regulation.

For this reason, in the present study intravascular, extracellular, and intracellular fluid volumes were compared in nonobese and obese hypertensive patients. In the latter group fluid volumes were investigated before and after weight reduction, using a low calorie diet with moderate sodium intake.

## Methods

**Patients:** The study was performed in 50 men: 18 normal subjects and 32 patients with sustained essential hypertension. The age range was 20 to 60 years in both groups. The 50 men were untreated or had their therapy discontinued at least 4 weeks before the study. During this period, they maintained their weight within a 2 to 3 kg range. All were hospitalized for 6 days on a 90 mEq/day sodium diet. On the basis of weight, sodium, and urinary output, a steady sodium balance was assumed.

Subjects were considered normal when, on the basis of usual clinical and biologic investigations, they had a constant diastolic pressure of <90 mm Hg. Patients were considered to have had essential hypertension when diastolic pressure repeatedly measured by indirect method was ≥100 mm Hg during the untreated ambulatory period. Blood pressure determinations were done using both a normal-sized (14 by 60 cm) and a large pressure cuff (according to degree of obesity[1]), thus excluding borderline hypertension in obese patients.

Investigations included measurements of blood and urinary electrolytes, creatinine clearance, fasting blood sugar, and serum cholesterol and triglycerides, liver function tests, urinary catecholamine determinations and timed intravenous pyelography. The 32 hypertensive patients were all diagnosed as having moderate essential hypertension. Patients who had diabetes mellitus requiring insulin, cardiac disease, alcoholism, drug addiction, or psychiatric problems were excluded from the study. The mean creatinine clearance rate was 97 ± 9 ml/min/1.73 $m^2$ (±1 standard error of the mean).

According to the level of body weight, hypertensive patients were divided into 2 subgroups: nonobese (16) and obese (16). Obese patients weighed >20% above ideal weight, defined on the basis of age, sex, height, and body build, according to Metropolitan Life Insurance tables.[4] Nonobese patients weighed <10% above ideal weight. Clinical characteristics are indicated in Table I.

The protocol was approved by the Institut National de la Santé et de la Recherche Médicale (INSERM). Informed consent was obtained from the patients after a detailed description of the procedure.

The hemodynamic and fluid volume studies were performed on the third and fourth days of hospitalization, respectively. After overnight fasting, patients were brought to the laboratory without premedication at 8 A.M. Body weight was determined without shoes and in underwear only. Hemodynamic and fluid volume investigations were performed in the supine position after 10 minutes of rest.

**Hemodynamic variables:** An 18 gauge needle was placed in the brachial artery after local anesthesia. A catheter was

introduced into the antecubital vein to the juncture with the subclavian vein for injection and samplings. Cardiac output was measured according to the dye-dilution method, as previously described.[5] Intraarterial blood pressure recorded throughout the study was used as the pressure reference for each patient. At the time of the investigation, diastolic blood pressure was ≥90 mm Hg in 10 nonobese hypertensive patients and in 8 obese hypertensive patients.

**Fluid volume determinations:** Inulin, albumin, and antipyrine spaces were evaluated simultaneously.

**Inulin space:** Extracellular fluid volume (EFV) was approximated to the distribution volume of inulin. The inulin space was estimated by the simple injection technique according to Ladegaard and Pederson.[6] Forty-five ml of 10% inulin solution were injected intravenously over 4.5 minutes. Blood samples were taken before administration and repeated 5, 7, 10, 15, 30, 45, 60, 79, 90, 105, 120, 150, and 180 minutes after the beginning of the injection. Inulin was measured by using the method of Roe et al.[7] The plasma inulin concentration was plotted against time on a semilogarithmic scale. A curvilinear curve was obtained and divided into 2 exponential functions according to the feathering technique.

The 2-exponential model, more valid than the monoexponential model, was used for the calculation of the inulin space and clearance.[6] The inulin distribution volume equals the product of the total clearance and the mean transit time calculated from the classical equations.[6] Inulin space and clearance were corrected for the plasma water content by a factor $p = 100 - 0.73$ pp, where 0.73 is the volume of liquid displaced by 1 g of protein in 100 ml of plasma and pp is the plasma protein concentration.[6] The reproducibility of the method was 9.5 ± 3.6%. The validity of the inulin space as an index of extracellular fluid volume has been discussed in detail elsewhere.[8,9] For this, simultaneous determinations of the bromide and the inulin space were performed. A strong positive correlation between the 2 indexes was shown. In comparison with bromide space, inulin space underestimates extracellular fluid volume by approximately 70 ± 8 ml/kg. The underestimation is similar in normotensive and hypertensive subjects.

**Albumin space[8,9]:** Plasma volume was evaluated by the isotopic dilution method using radioactive iodine-131 albumin. After withdrawal of a control sample, 3 μCi was injected at zero time; 10 minutes later a single blood sample was taken for counting and volume estimations. Plasma volume was corrected for water content by the same factor used for inulin space. Total blood volume was calculated from plasma volume and hematocrit. In 25 patients, albumin space was evaluated using serial consecutive blood samples. Activity was plotted against time. The volume was calculated from the extrapolated activity at zero time. The value was lower than that obtained from the single 10-minute sample, but the difference was not significant in normotensive (2 ± 1%) and hypertensive subjects (5 ± 3%). Thus, only the determination of intravascular volume with the single 10-minute sample was used in the present study.

**Antipyrine space:** Total body water (TBW) was estimated from the distribution volume of antipyrine, according to the method of Soberman et al.[10] For this, 1 mg of antipyrine was injected intravenously within 3 minutes. Blood samples were subsequently withdrawn at 0, 1, 2, 3, 4, and 5 hours. The antipyrine plasma level was evaluated using a previously described photometric method involving a precipitation procedure.[11] The logarithm of the plasma concentration was plotted against time and yielded a linear relation. The antipyrine clearance was calculated from the slope of the curve. Total body water was calculated as the ratio between the amount of antipyrine injected and the antipyrine plasma concentration extrapolated at zero time. Correction for plasma water content was performed as for inulin space. The reproducibility of the method was 8.3 ± 3.4%. Previous studies[10–12] have shown that the antipyrine and the deuterium spaces were similar and that the antipyrine method was valid even in obese subjects and in patients with abnormal depots of fluids.

**Dietary program:** Right after the investigations, 9 of the 16 obese hypertensive patients were placed on a dietary program. The intention was to obtain a 10 to 15% reduction of body weight in 1 month, using a low calorie diet with a moderate sodium intake. The daily diet contained 1,000 calories and consisted of 35% proteins, 35% carbohydrates, and 30% fats. Sodium intake was 90 mEq/day. During the follow-up period, which lasted for 4 weeks, all patients visited the clinic weekly. At each visit, blood pressure and weight were measured. All patients were interviewed by the dietician to ensure compliance with the dietary program. The specific dietary components were individually tailored to each patient on the basis of his regular dietary habits, after an interview by the dietician. No other treatment or concomitant hypotensive drug therapy was added. The hemodynamic and fluid variables were reexamined after weight reduction with the same procedure as in the first investigation, that is, on the third and fourth days of hospitalization, the dietary program being maintained.

**Presentation of results and statistical evaluation:** Fluid volumes were expressed in milliliters and milliliters per kilogram for presentation of the results. Body surface area could also be used, but this calculated variable is strongly correlated to body weight.[5] In fact, since the values of fluid volumes in obese and nonobese hypertensive patients depend greatly on the distribution of sex and on the choice of reference frame for the body size,[12–14] only the partition indexes of fluid volumes were studied in the present investigation. For this, intracellular body water (IBW) and interstitial fluid volume (IFV) were respectively calculated as TBW-EFV and EFV-PV differences. Three partitions indexes were defined: PV/IFV, partition index of extracellular fluid volume; EFV/TBW, partition index of total body water; and IBW/IFV, partition index between intracellular body water and interstitial fluid volume.

Means, standard errors of the mean, and correlation coefficients were calculated according to standard statistical methods.[15] Regression analysis was performed using the

least-squares methods. Differences in means were assessed by Student's $t$ test in comparison with control values. When comparing the 3 groups (control subjects, and nonobese and obese hypertensive patients), the validity of the statistical analysis was confirmed by an analysis of variance. A p value of <0.05 was accepted as being statistically significant.

## Results

### Basal Values

**Hemodynamic variables (Table II):** Systolic and diastolic blood pressures were significantly increased in hypertensives ($p < 0.001$, $p < 0.01$) in comparison with normal subjects. Blood pressure was similar in obese and nonobese hypertensive patients. In control subjects and in hypertensive patients, cardiac index and heart rate were not significantly different.

**Fluid volumes (Table III):** When the absolute values of fluid volumes (in milliliters) were compared in obese and in nonobese hypertensive patients, total body water, plasma volume, and intracellular body water were significantly higher ($p < 0.05$) in the obese hypertensive group, while extracellular and interstitial fluid volumes were similar.

The PV/IFV ratio was the same in control subjects and hypertensive patients. Figure 1A illustrates that in patients with hypertension the PV/IFV ratio was negatively correlated with mean arterial pressure ($r = -0.42$, $p < 0.05$).

In the obese hypertensive group, the EFV/TBW ratio was significantly lower ($p < 0.05$) and the IBW/IFV ratio significantly higher ($p < 0.01$) than in control subjects. No comparable results were observed for the nonobese hypertensive patients. Figure 2 shows the individual values of the IBW/IFV ratio in the 3 groups of subjects: 8 of the obese hypertensive patients had values above the upper limit of normal.

**TABLE III Fluid Volumes in Basal Conditions**

| IBW/IFV | 3.1 ± 0.3§ | 3.5 ± 0.2 | 4.42 ± 0.25 |

Note that when the absolute values of fluid volumes (ml) were compared in obese and nonobese hypertensives, TBW, PV, and IBW were significantly higher ($p < 0.05$) in obese hypertensive patients, while EFV and IFV were similar.

Values are means ±1 standard error of the mean. * $p < 0.05$, † $p < 0.001$, ‡ $p < 0.01$, compared with control subjects. § $n = 8$ for the determination of total body water in control subjects.

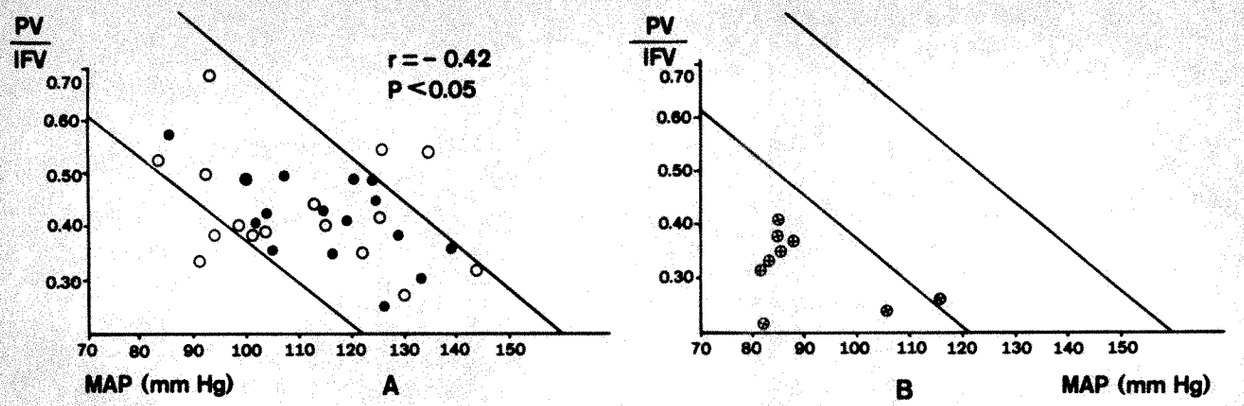

**FIGURE 1.** Relation between mean arterial pressure (MAP) and the ratio between plasma volume (PV) and interstitial fluid volume (IFV) in hypertensive patients. The relation is presented within the 95% confidence limits of the normal curve. **A,** the relation in patients studied in basal conditions. **B,** the individual values after weight loss. **Black circles** represent nonobese hypertensive patients; **white circles,** obese hypertensive patients; and **circles with crosses,** obese hypertensive patients after body weight reduction.

### Effects of Body Weight Reduction in Obese Hypertensive Patients

**Hemodynamic variables (Table IV):** After body weight reduction, blood pressure and heart rate decreased significantly ($p < 0.01$ and $p < 0.05$), whereas the cardiac index did not change significantly. Total peripheral resistance increased slightly. Plasma and urinary electrolyte levels were similar at the beginning and the end of the dietary program. No significant change in antipyrine and inulin clearance was observed.

**Fluid volumes (Table V):** When the absolute values of fluid volumes (in milliliters) were compared before and after weight reduction, plasma volume and total and intracellular body water decreased, whereas extracellular and interstitial fluid volumes increased significantly ($p < 0.05$). The latter result was observed even when extracellular and interstitial fluid volumes were expressed in milliliters per kilogram.

The PV/IFV ratio significantly decreased after weight reduction ($p < 0.05$). Figure 1B indicates that after body weight reduction, all patients were under the 95% confidence limits of the negative PV/IFV-blood pressure relation observed before weight loss (compare Fig. 1A and 1B).

The EFV/TBW ratio significantly increased ($p < 0.01$). The IBW/IFV ratio significantly decreased ($p < 0.01$) (Fig. 3) and approximated the values of controls.

## Discussion

Several difficulties arise from reported data that interpret fluid volume in obese hypertensive patients.[1,13,14] First, plasma volume was found to be increased when expressed in milliliters and milliliters per unit of height, but decreased when expressed in milliliters per kilogram. This is possibly due to the smaller blood volume per unit weight of adipose tissue compared with lean body mass.[13,14] Second, in most studies, only intravascular volume (and not interstitial and intracellular fluid volumes) was taken into consideration. This point is important since Moore et al[12] have shown that the increase in fluid volumes with body weight is different for total body water, plasma volume, and extracellular fluid volume: for the same increase in body weight, the increase in total body water and plasma volume is higher than the corresponding increase in extracellular fluid volume. This finding suggests that only the concomitant study of the 3 spaces is relevant in investigating fluid volumes in obese hypertensive patients.

In the present study, total body water, plasma volume, and extracellular fluid volume were simultaneously investigated. Further, since the problem of the reference frame to express fluid volumes is difficult to overcome,[13] only the indexes of partition of fluid volumes were analyzed. Thus, the present comments mainly concern the PV/IFV and the IBW/IFV ratios.

**The PV/IFV ratio:** Several discrepancies exist in the literature for the evaluation of the PV/IFV ratio in patients with essential hypertension. The ratio was found to be decreased[8,16,17] or normal.[18] These differences can be explained easily on the basis of the degree of severity of the disease. We previously showed that the PV/IFV ratio in hypertensive patients was negatively related to the level of blood pressure.[8] Thus, the PV/IFV ratio is expected to be normal in mild hypertension[18] and decreased in more severe hypertension.[8,16,17] In the present study, the ratio was within the normal range in our hypertensive patients, but was negatively correlated with mean arterial pressure. Since 29 of the 47 patients had a diastolic pressure <90 mm Hg, our results exactly reflect the negative correlation between the PV/IFV ratio and blood pressure in patients with hypertension.

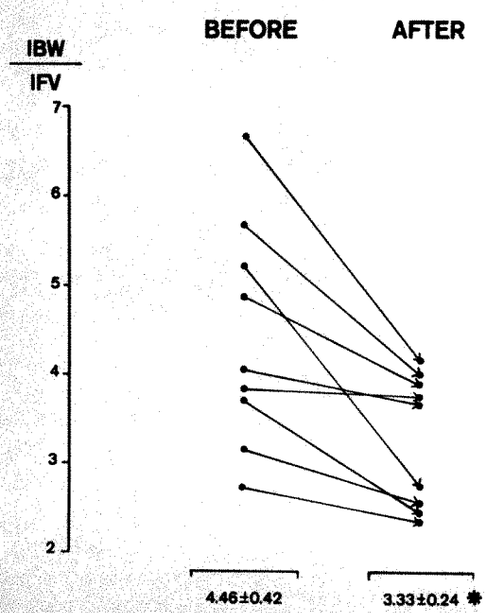

**FIGURE 3.** Obese hypertensive patients: study of the ratio between intracellular body water (IBW) and interstitial fluid volume (IFV) before and after weight reduction (*$p < 0.01$).

The altered partition of extracellular fluid volume in hypertension has been attributed to a shift of intravascular volume toward the interstitial component of the extracellular fluid volume space.[13] Since an increase in the transcapillary escape of albumin and Evans blue dye toward interstitial fluid volume[19,20] has been observed, the shift has been assumed to reflect a disturbed capillary filtration, due to an abnormality in the precapillary sphincters or in venular tone, or both.[13] However, this interpretation concerns only hypertensive patients studied in basal conditions. In particular, in the present study the decreased PV/IFV ratio after weight reduction could hardly be due to a disturbance in the capillary exchange. First, only minimal changes in plasma volume were observed. Second, after body weight reduction using a low calorie diet and moderate sodium intake, the values of the PV/IFV ratio were not inside but below the confidence limits of the curve relating PV/IFV to mean arterial pressure (Fig. 1). This result strongly suggests that the change in the PV/IFV ratio in obese hypertensive patients is related to a peculiar disturbance of interstitial fluid volume, as suggested by the study of the EFV/TBW and IBW/IFV ratios.

**EFV/TBW and IBW/IFV ratios:** The distribution of fluid volumes between the intracellular and the extracellular spaces has been poorly investigated in patients with obesity and in hypertension.[12–18] Moore et al[12] tried to evaluate the degree of hydration of adipose tissue in overweight patients. This investigator showed that if normal obesity tissue contained a large component of water, this water would be extracellular in position and rich in sodium. Therefore, if adipose tissues were very rich in water, then all obese patients should have a higher EFV/TBW ratio. On the basis of this ob-

servation, Moore et al[12] divided obese subjects into those with healthy (normal ratio) and those with nonhealthy (high ratio) obesity. However, the study was based on a small group of 9 patients, 4 men and 5 women, only 1 of whom had hypertension. On the other hand, Bauer and Brooks[18] showed that the EFV/TBW ratio was decreased in hypertensive patients; however, they failed to relate this observation to the excess weight problem existing in their patients.

The present investigation was the first to observe an altered partition of body water between the intra- and extracellular spaces in obese hypertensive patients. The most consistent finding of the study was the increase in the IBW/IFV ratio found in obese hypertensive patients. This increase might be caused either by an intracellular body water level which is too high for the level of interstitial fluid volume or by an IFV which is too low for the level of intracellular body water. However, several observations in the present study could favor the former possibility. First, in agreement with the previous observations of Moore et al,[12] extracellular and interstitial fluid volume were poorly related with body weight in comparison with total body water, plasma volume, and intracellular body water. In this respect, Table III shows that when the absolute values of fluid volumes (in milliliters) were compared in obese and nonobese hypertensive patients, total body water, plasma volume, and intracellular body water were significantly different, while extracellular and interstitial fluid volumes were similar. Second, the decrease in the IBW/IFV ratio after weight loss was due to an increase in interstitial fluid volume, which was not dependent on the reference frame to express fluid volumes (milliliters or milliliters per kilogram). Thus, the increase in interstitial fluid volume after weight loss was due to a shift of fluid volume from the intracellular to the interstitial spaces. Although the mechanism of the shift is difficult to explain, our findings strongly suggest that an absolute increase in intracellular body water exists in obese hypertensive patients when they do not undergo body weight reduction.

The increased water cell content of obese hypertensive patients is difficult to explain. The changes that were described in arterial pressure as well as with the fluid partitions could be ascribed not only to weight reduction but also to the peculiar effects of the caloric and moderate sodium restrictions, with the additional expected consequences on the hormonal and metabolic factors and on the sympathetic nervous system.[21,22] At least 3 hypotheses could be inferred from the literature. First, the role of renin could be suggested from 2 observations: (1) an increase in intracellular body water has been shown in patients with normal (but not low) renin hypertension,[18] and (2) renin decreases after weight reduction in obese patients.[23] Second, the role of sympathetic nervous activity is suggested by the hemodynamic effects of body weight reduction: the decrease in the IBW/IFV ratio after a decrease in body weight was associated with a decrease in blood pressure. Whether the decrease in pressure was due to a reduction in cardiac output or total peripheral resistance,[21] a significant decrease in heart rate was observed.[21-25] This suggests a reduction in sympathetic nervous activity, a fact which has been well documented after calorie restriction.[26,27] Finally, abnormalities in the activity of the sodium-potassium pump have also been described both in obesity[28] and in hypertension[29] and could possibly influence the partition of fluid volumes.

**Conclusion:** Whether the shift of fluid volume is a manifestation of obesity and loss of weight in general or has a particular relation to hypertension, the present findings suggest that 2 varieties of altered partition of fluid volumes might be observed: the decreased PV/IFV ratio, directly related to the level of blood pressure, and the increased IBW/IFV ratio, mainly influenced by the excess weight observed in patients with essential hypertension.

# Relation of Hemodynamic Load to Left Ventricular Hypertrophy And Performance in Hypertension

RICHARD B. DEVEREUX, MD, DANIEL D. SAVAGE, MD, PhD, IRENE SACHS, BS, and JOHN H. LARAGH, MD

**Left ventricular hypertrophy and dysfunction in patients with hypertension are often poorly related to the level of blood pressure. To evaluate the reasons for this, 100 untreated patients (44 ± 14 years) with essential hypertension were studied using cuff blood pressure and quantitative echocardiography to measure left ventricular mass index and end-diastolic relative wall thickness as 2 indexes of left ventricular hypertrophy. Left ventricular hypertrophy, as measured by either left ventricular mass index or end-diastolic relative wall thickness, correlated weakly with all indexes of blood pressure including systolic, diastolic, and mean blood pressure ($r = 0.16$ to $0.32$). In contrast, end-diastolic relative wall thickness, an index which assesses the severity of concentric hypertrophy, showed a closer direct relation with total peripheral resistance ($r = 0.52$, $p < 0.001$) and a significant inverse relation with cardiac index ($r = -0.47$, $p < 0.001$). Left ventricular performance as assessed by fractional systolic shortening of left ventricular internal dimensions was not significantly related to left ventricular mass index, blood pressure, or peak systolic wall stress, but declined significantly with increasing mean systolic wall stress ($r = -0.42$, $p < 0.001$) and even more with increasing end-systolic wall stress ($r = -0.71$, $p < 0.001$).**

**It is concluded that in patients with hypertension (1) left ventricular hypertrophy is correlated only modestly with measurements of resting blood pressure; and (2) the classic pattern of concentric left ventricular hypertrophy, as measured by relative wall thickness, is more closely related to the "typical" hypertensive abnormality of elevated peripheral resistance, suggesting that these anatomic and hemodynamic changes may be pathophysiologically interdependent. Furthermore, left ventricular performance declines when the pressure overload in hypertension is not offset by compensating hypertrophy, allowing wall stresses to increase.**

Progression of hypertensive heart disease from adaptive left ventricular hypertrophy with compensated ventricular function to severe hypertrophy with left ventricular failure is thought to be related to the severity and duration of hypertension. In patients with hypertension, increasing levels of blood pressure have been associated with greater anatomic,[1] echocardiographic,[2–5] or electrocardiographic[6,7] evidence of left ventricular hypertrophy. These abnormalities become more marked in the presence of prolonged duration of hypertension, or evidence of damage to other target organs.[2,8,9] Thus, moderate left ventricular hypertrophy is associated with reduced exercise capacity[10] and more severe hypertrophy with congestive heart failure in man.[1] In most patients with moderate degrees of hypertension, resting left ventricular performance has been reported to remain normal,[2,11] suggesting successful compensatory hypertrophy, whereas left ventricular function may deteriorate in the face of more severe hypertension.[2]

These observations support the applicability to hypertension of Meerson's hypothesis that heart disease evolves through stages of physiologic hyperfunction and compensatory hypertrophy before ventricular failure supervenes.[12] However, most studies have reported group averages, which obscure the great variability in cardiac findings among patients with a similar level of hypertension. Thus, it is common to encounter patients with moderately severe hypertension but no evidence of left ventricular hypertrophy. In other patients only mild hypertension precedes the development of myocardial failure. Partial explanations for these discordances have been provided by reports of diverse hemodynamic profiles in hypertension[13–15] and by the finding that left ventricular function in patients with hypertension or aortic stenosis was regulated by levels of left ventricular wall stresses, which are determined by the relation between hemodynamic load and left ventricular hypertrophy.[16–18] It has further been suggested by Folkow[19] and Lund-Johansen[20] that alterations in cardiac anatomy caused by hypertension might influence the hemodynamic pattern in patients with hypertension. We have undertaken the present study

to answer 2 questions raised by the foregoing observations: (1) Do hemodynamic factors other than the level of blood pressure influence the degree and pattern of hypertensive left ventricular hypertrophy? and (2) What is the relation between the degree of left ventricular hypertrophy and cardiac performance in hypertensive subjects? Specifically, does the level of left ventricular wall stress, governed by the match between pressure overload and mycardial hypertrophy, regulate cardiac function in patients with essential hypertension?

## Methods

**Patients:** A total of 100 patients with essential hypertension underwent echocardiography, cardiovascular history, and physical examination. The study population consisted of 69 men and 31 women aged 18 to 69 years (mean 44 ± 14) with a body surface area of 1.50 to 2.8 $m^2$ (mean 1.90 ± 0.29). At the time of the study, no patients had received any antihypertensive or other cardioactive medication for at least 3 weeks. All patients with evidence by history, physical examination, or electrocardiography of coronary artery disease or significant valvular disease were excluded, but 3 patients had mitral valve prolapse with no evidence on physical examination or echocardiography of significant mitral regurgitation. Blood pressure was determined by cuff sphygmomanometry at the time of the echocardiogram, using phases 1 and 5 of the Korotkoff sounds.

**Echocardiographic studies:** M-mode echocardiograms were performed in the partial left decubitus position using 13-mm, 2.25-mHz transducers and either a Picker Echoview 80C or Smith-Kline Ekoline 20A echograph with a Honeywell 1856A strip chart recorder on light-sensitive paper at 50 mm/s. Simultaneous visualization throughout the cardiac cycle of interventricular septal thickness (IVS), left ventricular internal dimension (LVID), and posterior wall thickness (PWT) was sought at or just below the tips of the mitral valve leaflets. All echocardiograms were coded and read blindly and independently by 2 investigators (RBD and DDS). Differences between readers of 1 mm in measurement of IVS and PWT and of 2 mm in measurement of LVID were averaged; greater differences were resolved by review of the coded echocardiogram.

At end-diastole, 2 sets of points were identified. The first was selected according to the recommendation of the American Society of Echocardiography for measurement of IVS, LVID, and PWT.[21] End-systolic measurements were also made using American Society of Echocardiography criteria. The second set of end-diastolic points was selected at the peak of the R wave of the simultaneous electrocardiogram using the alternative Penn convention, in which the thickness of endocardial interfaces is excluded from IVS and PWT, and included in LVID.[22] Left ventricular mass (LVM) was calculated using Penn convention measurements in the following equation[22]: $LVM = 1.04\,[(LVID_p + PWT_p + IVS_p)^3 - (LVID_p)^3] - 14$ g. Relative wall thickness (RWT = 2PWT/LVID) at end-diastole and end-systole was calculated as an index of concentric left ventricular hypertrophy.[23] Left ventricular performance was assessed by measurement of systolic fractional shortening of the left ventricular internal dimension: Fractional shortening = $(LVID_d - LVID_s)/LVID_d$. Left ventricular volumes at end-diastole (LVEDV) and end-systole (LVESV) were estimated by the cube function formula[24] and used to calculate stroke volume as LVEDV − LVESV; cardiac output was calculated as stroke volume × heart rate. Total peripheral resistance (TPR) was calculated by the following formula[25]: TPR = (mean BP (mm Hg) ×80)/cardiac output (liters), where BP = blood pressure.

Since afterload is best expressed as wall stress, peak and end-systolic meridional wall stress were calculated by the noninvasive method of Wilson et al,[26] using echocardiographic dimensions and cuff blood pressure in the following formulas: Peak systolic stress = $0.86\,[(0.334 \times LVID_d \times \text{systolic BP})/PWT_d \times (1 + PWT_d/LVID_d)] - 27 \times 10^3$ dynes/$cm^2$ and End-systolic stress = $0.98\,[(0.334 \times LVID_s \times \text{systolic BP})/PWT_s \times (1 + PWT_s/LVID_s)] - 2 \times 10^3$ dynes/$cm^2$. In addition, the mean LV systolic wall stress index of Quinones et al[27] was calculated by use of the following formula: Mean wall stress index = Systolic BP × $[(LVID_d + LVID_s)/2(PWT_d + PWT_s)]$.

**Statistics:** A Hewlett-Packard programmable calculator was used to perform least-squares linear regression and Student's $t$ test.[28]

## Results

**Hemodynamics:** Systolic blood pressure was 154 ± 18 mm Hg, diastolic pressure was 90 ± 10 mm Hg, and mean blood pressure 117 ± 11 mm Hg (range 105 to 157). The stroke index was 48 ± 12 ml/$m^2$ (normal value for this laboratory derived from 79 subjects[29] 45 ± 13, difference not significant [NS]), and the cardiac index was 3.45 ± 1.01 liters/min/$m^2$ (normal 3.15 ± 1.0, NS). Total peripheral resistance was 1,539 ± 445 ($p < 0.05$ versus normal 1,243 ± 235).

**Echocardiographic findings:** Interventricular septal thickness was 1.2 ± 0.3 cm and posterior wall thickness was 1.1 ± 0.2 cm ($p < 0.01$ versus normal values); left ventricular internal dimension was 5.0 ± 0.6 cm (NS versus normal findings of 4.8 ± 0.5 cm). Diastolic relative wall thickness was 0.43 ± 0.09 ($p < 0.02$ versus normal 0.34 ± 0.04), while systolic relative wall thickness was 1.08 ± 0.27 ($p < 0.02$ versus normal 0.90 ± 0.19). Left ventricular mass index ranged from 68 to 236 g/$m^2$ (mean = 118 ± 31 g/$m^2$, $p < 0.001$ versus normal of 70 ± 25 g/$m^2$). In 56 patients, left ventricular mass index fell within the 95% confidence limits of normal in this laboratory (≤119 g/$m^2$),[29] while the remaining 44 patients had definite left ventricular hypertrophy. Mean left ventricular fractional shortening in systole was 37 ± 6%, ranging from 23 to 55%; in only 3 patients did it fall below the 95% confidence limits of normal in this laboratory.

**Relation of hemodynamic variables to left ventricular hypertrophy:** To evaluate the relation between hemodynamic measurements and anatomic changes in patients with hypertension, we used 2 separate indexes of left ventricular hypertrophy, left ventricular mass index, and relative wall thickness. Only modest relations were observed between left ventricular mass index and mean blood pressure ($r = 0.32$, $p < 0.005$), systolic blood pressure ($r = 0.32$, $p < 0.005$), or diastolic blood pressure ($r = 0.26$, $p < 0.02$) (Table I). Left ventricular mass index exhibited a similar, relatively weak correlation with stroke index ($r = 0.27$, $p < 0.01$) or the product of mean blood pressure and stroke index, which approximates stroke work index ($r = 0.31$, $p < 0.005$). A slightly closer relation was observed between end-systolic volume index and left ventricular mass index ($r = 0.44$, $p < 0.001$).

Diastolic relative wall thickness, a measure of the severity of concentric left ventricular hypertrophy, showed an even weaker correlation with the level of

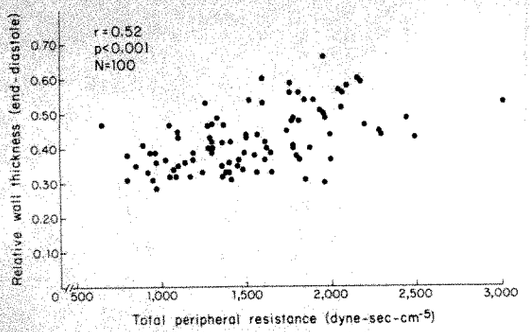

**FIGURE 1.** Left ventricular relative wall thickness at end-diastole (**vertical axis**) is directly related to total peripheral resistance (**horizontal axis**) in untreated hypertensive patients ($r = 0.52$, $p < 0.001$).

blood pressure ($r = 0.16$, $0.05 < p < 0.10$). In contrast, diastolic relative wall thickness exhibited a moderate direct correlation with total peripheral resistance ($r = 0.52$, $p < 0.001$) (Fig. 1). Furthermore, there was a significant inverse relation between increasing diastolic relative wall thickness and decreasing cardiac index ($r = 0.47$, $p < 0.001$) (Fig. 2). Figure 3 illustrates that for any level of blood pressure, patients with lower levels of cardiac index tended to have a higher relative wall thickness, and vice versa.

**Determinants of left ventricular performance:** Left ventricular performance, as measured by systolic fractional shortening of left ventricular internal dimension was unrelated to left ventricular mass index ($r = 0.04$, $p > 0.70$), mean blood pressure ($r = 0.04$, $p > 0.70$), or peak systolic wall stress ($r = 0.14$, $p > 0.10$). In contrast, there were highly significant negative correlations between mean or end-systolic left ventricular wall stress and left ventricular fractional shortening. Figure 4 demonstrates that left ventricular fractional shortening decreased moderately in patients as the mean systolic meridional wall stress index increased ($r = -0.42$, $p < 0.001$). Figure 5 depicts the even closer negative relation between left ventricular fractional shortening and end-systolic wall stress ($r = -0.71$, $p < 0.0001$).

**TABLE I Hemodynamic Determinants of Left Ventricular Hypertrophy in Hypertension**

| | Correlation Versus Left Ventricular Mass Index | | Correlation Versus End-Diastolic Relative Wall Thickness | |
|---|---|---|---|---|
| Variable | r | p | r | p |
| Mean blood pressure | 0.32 | <0.005 | 0.17 | NS |
| Systolic blood pressure | 0.32 | <0.005 | 0.16 | NS |
| Diastolic blood pressure | 0.26 | <0.02 | 0.14 | NS |
| Cardiac index | 0.26 | <0.02 | −0.47 | <0.001 |

## Discussion

The findings of the present study provide answers to the 2 questions posed at the outset. First, it is apparent that concentric left ventricular hypertrophy, as manifested by increased end-diastolic relative wall thickness, is directly related to peripheral resistance. Further, an inverse relation is observed between relative wall thickness and cardiac output in patients with mild to moderate hypertension. However, a second index of left ventricular hypertrophy—left ventricular mass index—was also increased in patients with hypertension, but was poorly correlated with hemodynamic measurements. Therefore, only a small portion of the variation in total left ventricular mass which occurs among such patients can be directly attributed to differences in resting blood pressure, cardiac output, or stroke work. In regard to the second question, it is apparent that left ventricular performance in hypertension is determined to a significant degree by the adequacy of left ventricular hypertrophy to compensate for the pressure overload. Thus, left ventricular systolic performance was inversely related to measures of wall stress, especially end-systolic wall stress, indicating that performance was depressed in patients in whom the hemodynamic load on the left ventricle had not elicited proportional ventricular hypertrophy.

**Hemodynamic determinants of hypertensive ventricular hypertrophy:** The finding that concentric left ventricular hypertrophy is more closely related to peripheral resistance than to blood pressure alone in patients with hypertension suggests that a direct, pathophysiologically important relation exists between these 2 classic features of hypertension. It is well known that although a high peripheral resistance, associated with a normal to low cardiac output, characterizes groups of patients with longstanding essential hypertension, hemodynamic profiles in hypertension are in fact quite diverse.[13–15,30] Thus, high cardiac output and relatively normal peripheral resistance are often seen in the early stages of essential hypertension,[31,32] in patients with hyperdynamic essential hypertension,[33] and in many patients with renal artery hypertension.[14] Both Folkow[19] and Lund-Johansen[20,32] have suggested that

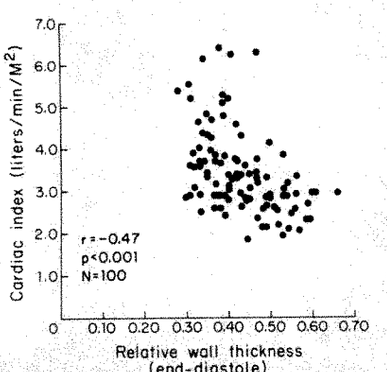

**FIGURE 2.** Cardiac index (**vertical axis**) is inversely related to left ventricular relative wall thickness at end-diastole (**horizontal axis**) ($r = -0.47$, $p < 0.001$).

changes in cardiac and peripheral vascular anatomy might play a role in the change in hemodynamic pattern to high peripheral resistance and normal to low cardiac output in patients with severe hypertension.

Most previous studies of hypertensive left ventricular hypertrophy have partially obscured this anatomic and hemodynamic variability by comparing group means for hemodynamic parameters and indexes of left ventricular hypertrophy. On average, our patients showed the expected increase in peripheral resistance, left ventricular mass and relative wall thickness with a normal cardiac index. However, the present study differs from previous reports in regarding both left ventricular mass and hemodynamic measurements as continuous variables. Our findings are in accord with the modest relation that has been shown in previous studies between blood pressure level and either heart size,[34] left ventricular mass,[4] or thickening of the left ventricular wall.[11,23,35] For the first time, we have also examined directly the relation of hypertensive cardiac hypertrophy to other hemodynamic variables, including stroke volume, end-systolic volume, and total peripheral resistance. In the present series, the relation between these other variables and left ventricular mass index were similar to or even closer than that between blood pressure and left ventricular mass.

This result is, at first glance, surprising, but can in fact be predicted from an examination of the role hemodynamic factors play in the genesis of myocardial hypertrophy. Both experimental studies[36,37] and theoretical analyses[38–42] indicate that left ventricular hypertrophy occurs in such a way as to normalize left ventricular wall stress. To accomplish this, increases in blood pressure (without a change in stroke volume) induce an increase in ventricular relative wall thickness, and hence absolute wall thickness. An increase in either stroke volume or end-systolic volume necessitates an increase in end-diastolic chamber volume and radius. Since, in the absence of a change in blood pressure, relative wall thickness stays constant, absolute left ventricular wall thickness increases in proportion to the increase in chamber radius. In any of these cases the left ventricular myocardial volume and mass are increased.

In the present series the severity of concentric left ventricular hypertrophy, as reflected by end-diastolic relative wall thickness, correlated better with total peripheral resistance than with the level of blood pressure. Furthermore, a significant inverse relation was observed between relative wall thickness at end-diastole and cardiac index. As illustrated in Figure 3, at any given level of blood pressure, patients with lower cardiac indexes tended to have higher end-diastolic wall thickness. A possible explanation for these relations is that increased left ventricular chamber stiffness due to increased relative wall thickness may impair diastolic left ventricular filling,[43,44] causing a secondary reduction in stroke volume and cardiac output. Such a reduction in cardiac output would, in turn, cause the measured level of blood pressure to be lower for any level of peripheral resistance than it would otherwise have been. Thus, an increased left ventricular relative wall thickness may participate in the reduction in cardiac output which is observed in many patients with severe hypertension. Such a reduction in cardiac output would, in turn, tend to moderate the increase in blood pressure produced by a given increase in peripheral resistance.

Despite the findings of the present study that resting blood pressure, stroke volume, and end-systolic volume are all related modestly to left ventricular mass in patients with essential hypertension, the majority of the total variability in left ventricular mass remains unex-

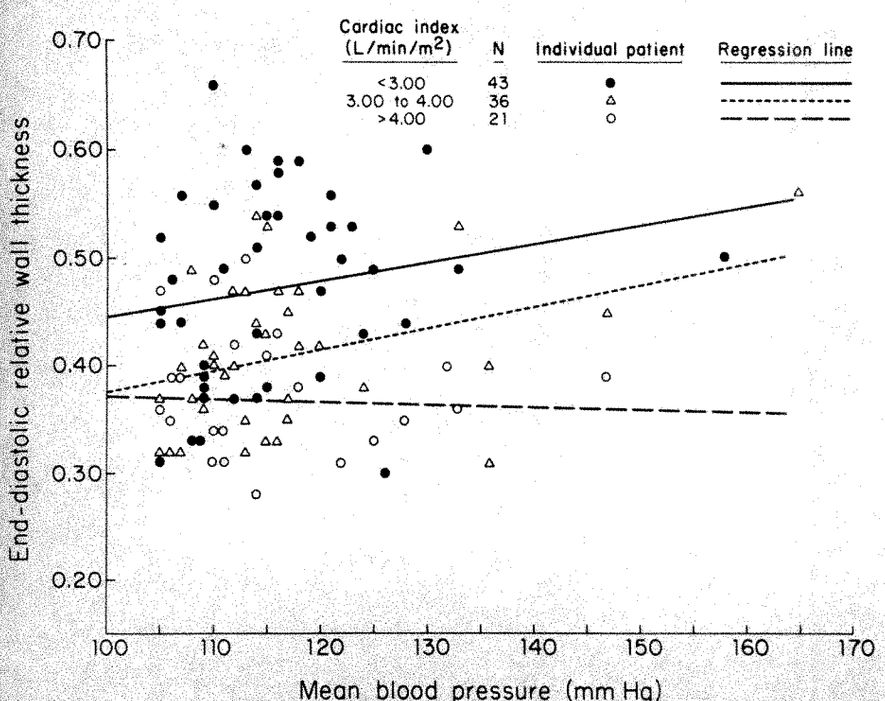

**FIGURE 3.** Relation between end-diastolic relative wall thickness (**vertical axis**) and mean blood pressure (**horizontal axis**), with patients classified according to level of cardiac index. At any level of blood pressure, relative wall thickness is greater in patients with a lower cardiac index.

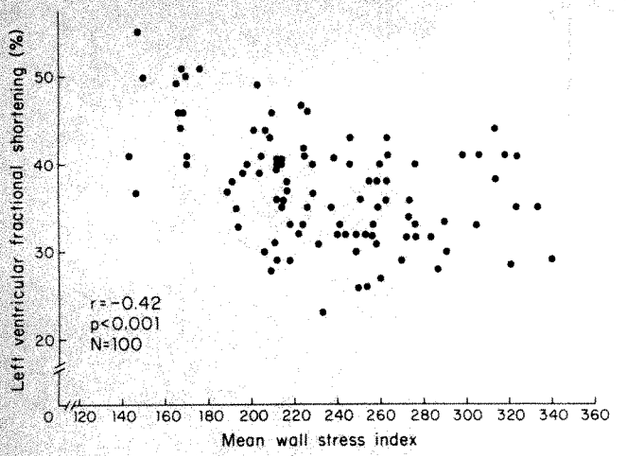

**FIGURE 4.** Left ventricular systolic performance, measured by the percent fractional shortening of left ventricular internal dimension (**vertical axis**) is inversely related to the mean left ventricular wall stress index (**horizontal axis**) ($r = -0.42$, $p < 0.001$).

plained by these parameters. Several factors may account for this. First, this study has used only resting hemodynamic measurements. It has been shown that office measurements of blood pressure may be poorly related to blood pressure throughout the day,[45–47] and that hypertensive patients have exaggerated blood pressure increased during exercise, occupational work,[48] or other forms of stress. Thus, the description of hemodynamic load in this and other studies is undoubtedly incomplete, since it is based solely on resting measurement. Second, myocardial contractility has an indirect effect on left ventricular hypertrophy. With impaired contractility, left ventricular end-systolic volume increases; as long as stroke volume remains constant, this necessitates an increase in end-diastolic volume, thus augmenting left ventricular hypertrophy, as we have demonstrated in this study. Third, age and increasing duration of hypertension[49,50] have been reported to increase left ventricular mass for a given level of blood pressure, whereas equally effective antihypertensive drugs have been reported to have disparate effects on left ventricular hypertrophy.[51–53] Finally, there is limited experimental evidence suggesting that norepinephrine or the renin-angiotensin system may play a direct role in cardiac hypertrophy beyond that mediated by their augmentation of blood pressure.[54–57]

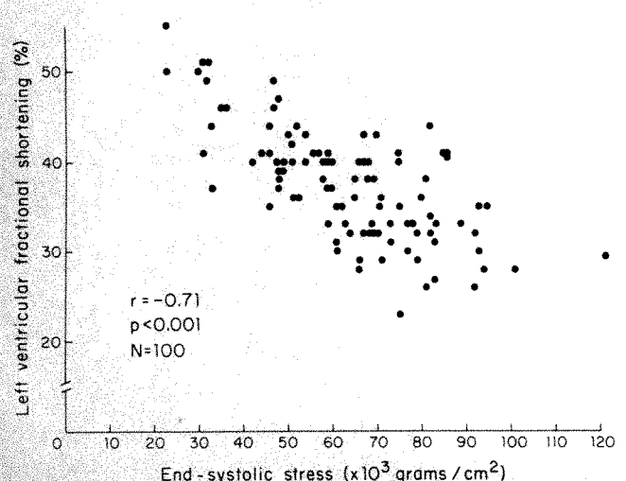

**FIGURE 5.** Left ventricular systolic performance, measured by percent fractional shortening of left ventricular internal dimension (**vertical axis**) decreases linearly with increasing end-systolic wall stress (**horizontal axis**) ($r = -0.71$, $p < 0.001$).

**Determinants of left ventricular performance in hypertension:** The present study confirms previous reports that left ventricular hypertrophy in patients with mild to moderate hypertension is largely a compensatory mechanism, since resting left ventricular fractional shortening was well maintained and was unrelated to abnormalities of left ventricular mass index. In contrast, left ventricular fractional shortening decreased moderately with increased mean systolic wall stress index (Fig. 4), and in a linear fashion with increasing end-systolic left ventricular wall stress (Fig. 5).

These findings demonstrate that patients with chronic hypertension and compensated left ventricular function show the same marked dependence of left ventricular performance on afterload, expressed as wall stress, as has been shown experimentally in response to acute interventions[58] and in patients with hypertension whose blood pressure is lowered acutely[59] or subacutely.[60] This effect would be largely masked had we relied on blood pressure alone as the measure of afterload. The closer relation of left ventricular shortening to estimated end-systolic stress than to peak systolic stress is concordant with a fundamental principle of cardiac mechanics: left ventricular contraction is terminated when wall stress (force) and chamber diameter intersect the ventricle's isometric force-length line.[61–63] Since peak systolic wall stress always occurs at a point below this sloping line, it would be expected to have only an indirect influence on left ventricular contraction, whereas, there is an obligatory relation between end-systolic wall stress and end-systolic left ventricular internal dimension in a given patient. The close negative relation observed in this study between end-systolic stress and left ventricular fractional shortening is the more impressive because it does not take into account absolute left ventricular internal dimension (the true abscissa), the effects variations in preload may have on left ventricular internal dimension (and hence on the fractional shortening required to reach a given end-systolic point), or the effects differences in intrinsic myocardial contractility or catecholamine levels might have on increasing or decreasing the end-systolic force-length line in individual patients.

**Clinical implications:** The echocardiogram provides a useful tool for assessing the anatomic and functional response of the heart in patients with hypertension.[64] Left ventricular relative wall thickness at end-diastole exhibits a significant relation with elevated total peripheral resistance, the typical hemodynamic abnormality of chronic hypertension. Furthermore, an inverse relation is observed between this index of concentric left ventricular hypertrophy and cardiac output, suggesting that increased chamber stiffness due to concentric hypertrophy may play a role in the reduction of cardiac

output in many patients with hypertension. In contrast, left ventricular mass index, another index of left ventricular hypertrophy, was not closely related to any hemodynamic measurement. Finally, left ventricular systolic performance was inversely related to mean and especially end-systolic left ventricular wall stress. These findings illustrate the extensive evaluation of cardiac anatomy and function in patients with hypertension that can be accomplished using clinically applicable echocardiographic methods.

**Acknowledgment:** We would like to thank Elizabeth M. Lutas, MD, Michael Jason, MD, and Thomas G. Pickering, MD for their critical reading of this manuscript and Virginia Burns for her assistance in preparation of this manuscript.

# yes... because it's Sanka®

BRAND
DECAFFEINATED COFFEE

Antihypertensive therapy often involves diet modification—restricting favorite foods and beverages. But there's one enjoyable beverage hypertensive patients can continue to enjoy: coffee.

Sanka® is 100% real coffee, but it's 97% caffeine-free. That's why it will not exacerbate underlying hypertension in patients who are bothered by too much caffeine.

And because Sanka® tastes good, it aids patient compliance. What's more, it's available in instant, freeze-dried and ground forms. It can even be found at restaurants in convenient single-service packages.

Nonstimulating Sanka® is ideally suited to many special diets. And physicians recommend it more than all other brands of decaffeinated coffee combined.

**Sanka®**
BRAND
DECAFFEINATED COFFEE

GF
GENERAL FOODS

**GOOD COFFEE THAT MAKES GOOD SENSE**

BIOTRONIK

Pacers in a class of their own™

# Kalos

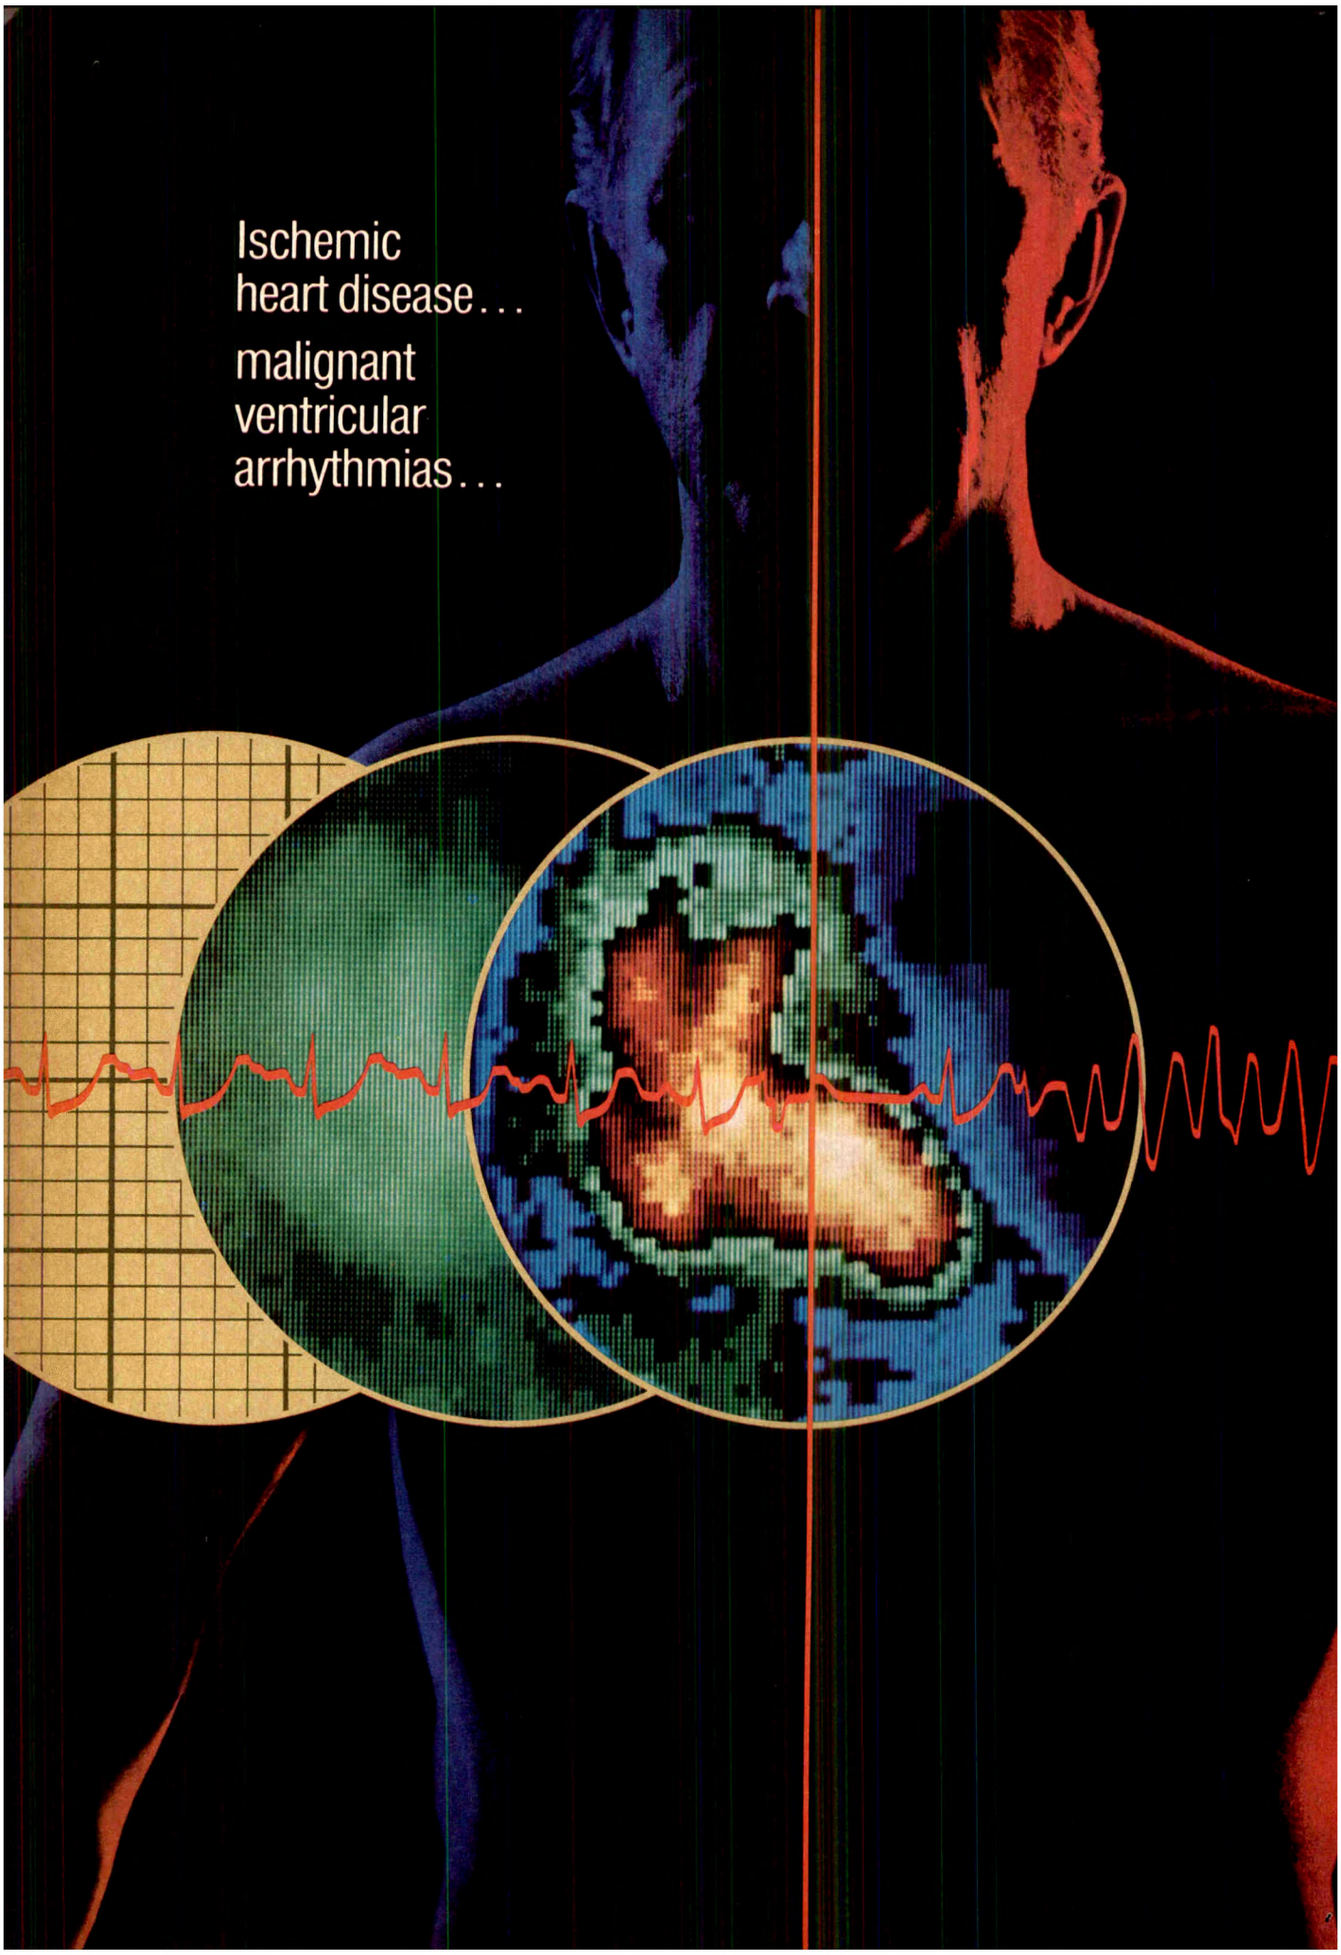
## a multi-programmable pacer with unique clinical features

- The thinnest pacer you can implant (only 8.8. mm) with an optimized geometrical shape* for more patient comfort
- Multi-programmable in all important parameters, V00/VVI, M
- Programmable high output
- Long service life
- The high reliability you have experienced with all BIOTRONIK pacers and products
- Available for unipolar and bipolar stimulation

BIOTRONIK pacers combined with the various BIOTRONIK active and passive fixation leads provide integrated pacing systems with the assurance of maximum reliability since all parts match one another and allow you to decide which system best suits the needs of each individual patient

8.8 mm

*Also available with the same thin, optimized geometrical shape, the standard VVI pacers **LEUKOS** and **LEIOS.**



For further information contact:

Ischemic
heart disease...
malignant
ventricular
arrhythmias...

# ZEROING IN ON THE CANDIDATE AT RISK

Frequent and complex forms of PVCs sharply increase the risk of sudden cardiac death (SCD) in patients with ischemic heart disease, especially in the presence of left ventricular dysfunction.[1,2]

## To reduce the risk of potentially fatal arrhythmias in such patients

# QUINAGLUTE® 324 mg DURA-TABS®

## (quinidine gluconate)

- If initially tolerated, can usually be taken successfully over long periods.[3]
- Demonstrated by programmed ventricular stimulation to be effective in accepted "standard" doses.[4]
- BID or TID dosage helps improve compliance while providing 24-hour antiarrhythmic activity.
- "As a rule, GI toxicity associated with quinidine gluconate is less frequent and less severe than that associated with quinidine sulfate."[5]

**QUINAGLUTE® (quinidine gluconate) DURA-TABS®**
**INDICATIONS AND USAGE:** Quinaglute (quinidine gluconate) Dura-Tabs are indicated in the prevention and/or treatment of:
**1. Ventricular arrhythmias:** Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock).
**2. Junctional (nodal) arrhythmias:** A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).
**CONTRAINDICATIONS:** 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.
**WARNINGS:** 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine.
2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered.
3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.
4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.
5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity.
7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.
8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.
**PRECAUTIONS: General:** The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk.
**Drug Interactions:**

| *Drug* | *Effect* |
|---|---|
| Quinidine with anticholinergic drugs | Additive vagolytic effect |
| Quinidine with cholinergic drugs | Antagonism of cholinergic effects |
| Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics | Alkalinization of urine resulting in decreased excretion of quinidine |
| Quinidine with coumarin anticoagulants | Reduction of clotting factor concentrations |
| Quinidine with tubocurare, succinylcholine and decamethonium | Potentiation of neuromuscular blockade |
| Quinidine with phenothiazines and reserpine | Additive cardiac depressive effects |
| Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin) | Decreased plasma half-life of quinidine |
| Quinidine with digoxin | Increased plasma concentrations of digoxin (see WARNINGS) |

**Carcinogenesis, Mutagenesis and Impairment of Fertility:** Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.
**Pregnancy:** *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.
**Nursing Mothers:** Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.
**Pediatric Use:** There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.
**ADVERSE REACTIONS:** Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea.
Less frequently encountered adverse reactions:
**Cardiovascular:** Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.
**Hematologic:** Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.
**Central Nervous System:** Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.
**Dermatologic:** Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.
**Hypersensitivity Reactions:** Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.

## CARDIOLOGIST—ELECTROPHYSIOLOGIST

CREIGHTON UNIVERSITY MEDICAL CENTER is offering a position for a cardiologist who has special interest and sufficient training in clinical electrophysiology to direct the Electrophysiology Laboratory. Present 11 man faculty group conducts a busy clinical, research and teaching program and desires to expand and improve the Electrophysiology Laboratory. This is a fulltime academic position with salary and academic rank commensurate with the level of training and experience.

Please Contact
SYED M. MOHIUDDIN, M.D., CHAIRMAN
SEARCH COMMITTEE FOR DIRECTOR OF
ELECTROPHYSIOLOGY LABORATORY
CREIGHTON UNIVERSITY CARDIAC CENTER
601 NORTH 30th STREET, OMAHA, NEBRASKA 68131

---

**CARDIOLOGIST WANTED** to associate with another sub-specialist with busy clinical practice. Midwestern town of 40,000 near large metropolitan area. Invasive and non-invasive skills necessary. Excellent salary, benefits and practice opportunity with eventual partnership. Reply with C.V., to Box 250, The American Journal of Cardiology, 875 Third Ave., New York, N. Y. 10022.

---

**CARDIOLOGIST**

wanted to join three man cardiology-internal medicine group in Piedmont North Carolina. Please send curriculum vitae and references to Box 245, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

---

**Northeastern Pennsylvania**—Dynamic practice opportunity in cardiology available. Modern JCAH approved, 160 bed general acute care hospital forty-five minutes northwest of Allentown, Pennsylvania, provides outstanding potential and opportunity in excellent geographic location for building specialty practice. Please send resume to Tod Mammuth, NEEMA Medical Services, Inc. 399 Market Street, Philadelphia, PA 19106 or call 800-523-0776 (outside PA) or 215-925-3511 (in PA).

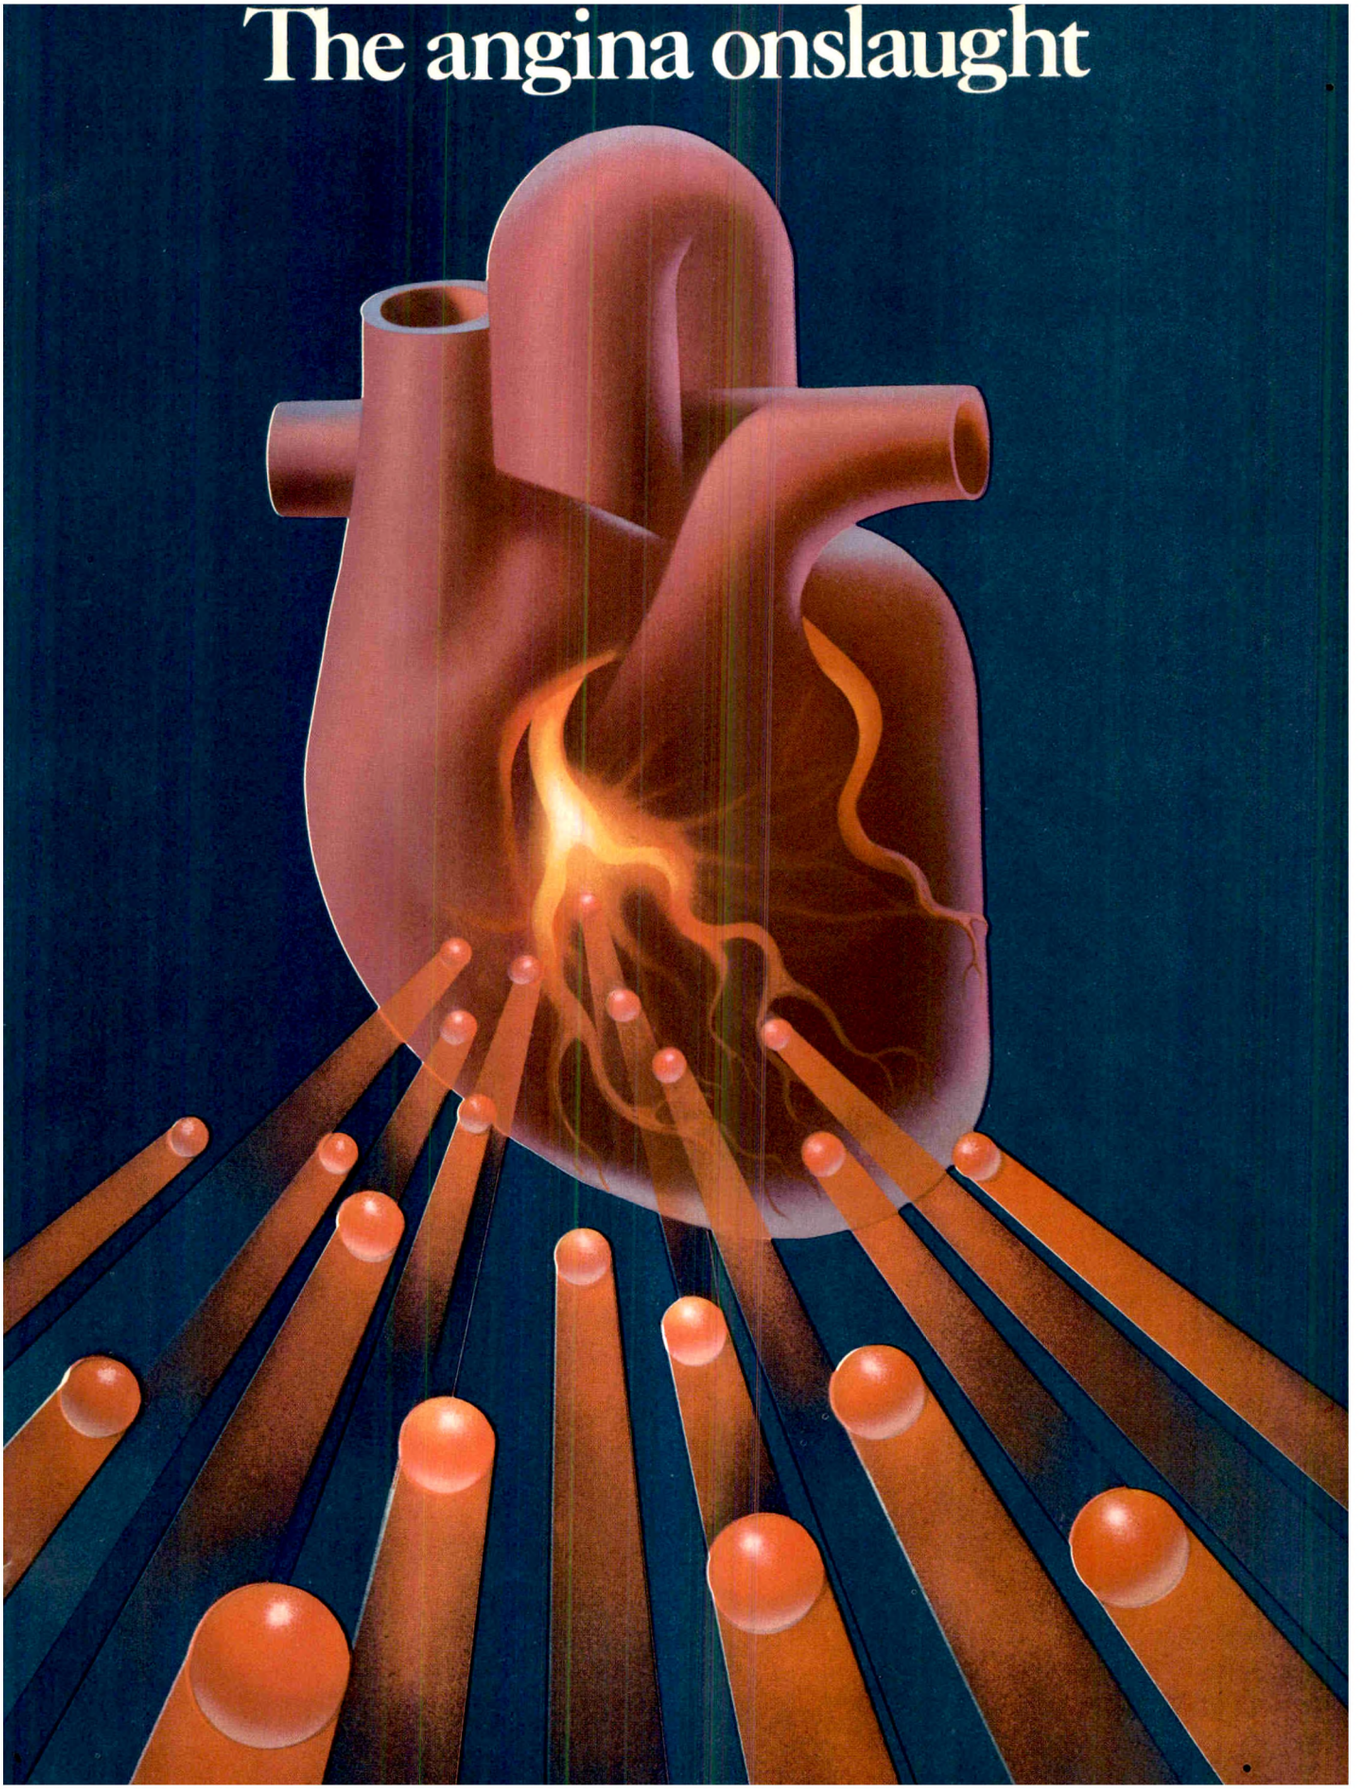
---

**CARDIOLOGIST**—For busy noninvasive and invasive cardiology practice. Medium sized city near resort area. 370 bed, modern, well-equipped hospital. Early partnership possible. Excellent starting salary. Write Box 255, The American Journal of Cardiology, 875 Third Ave., New York, N. Y. 10022.

---

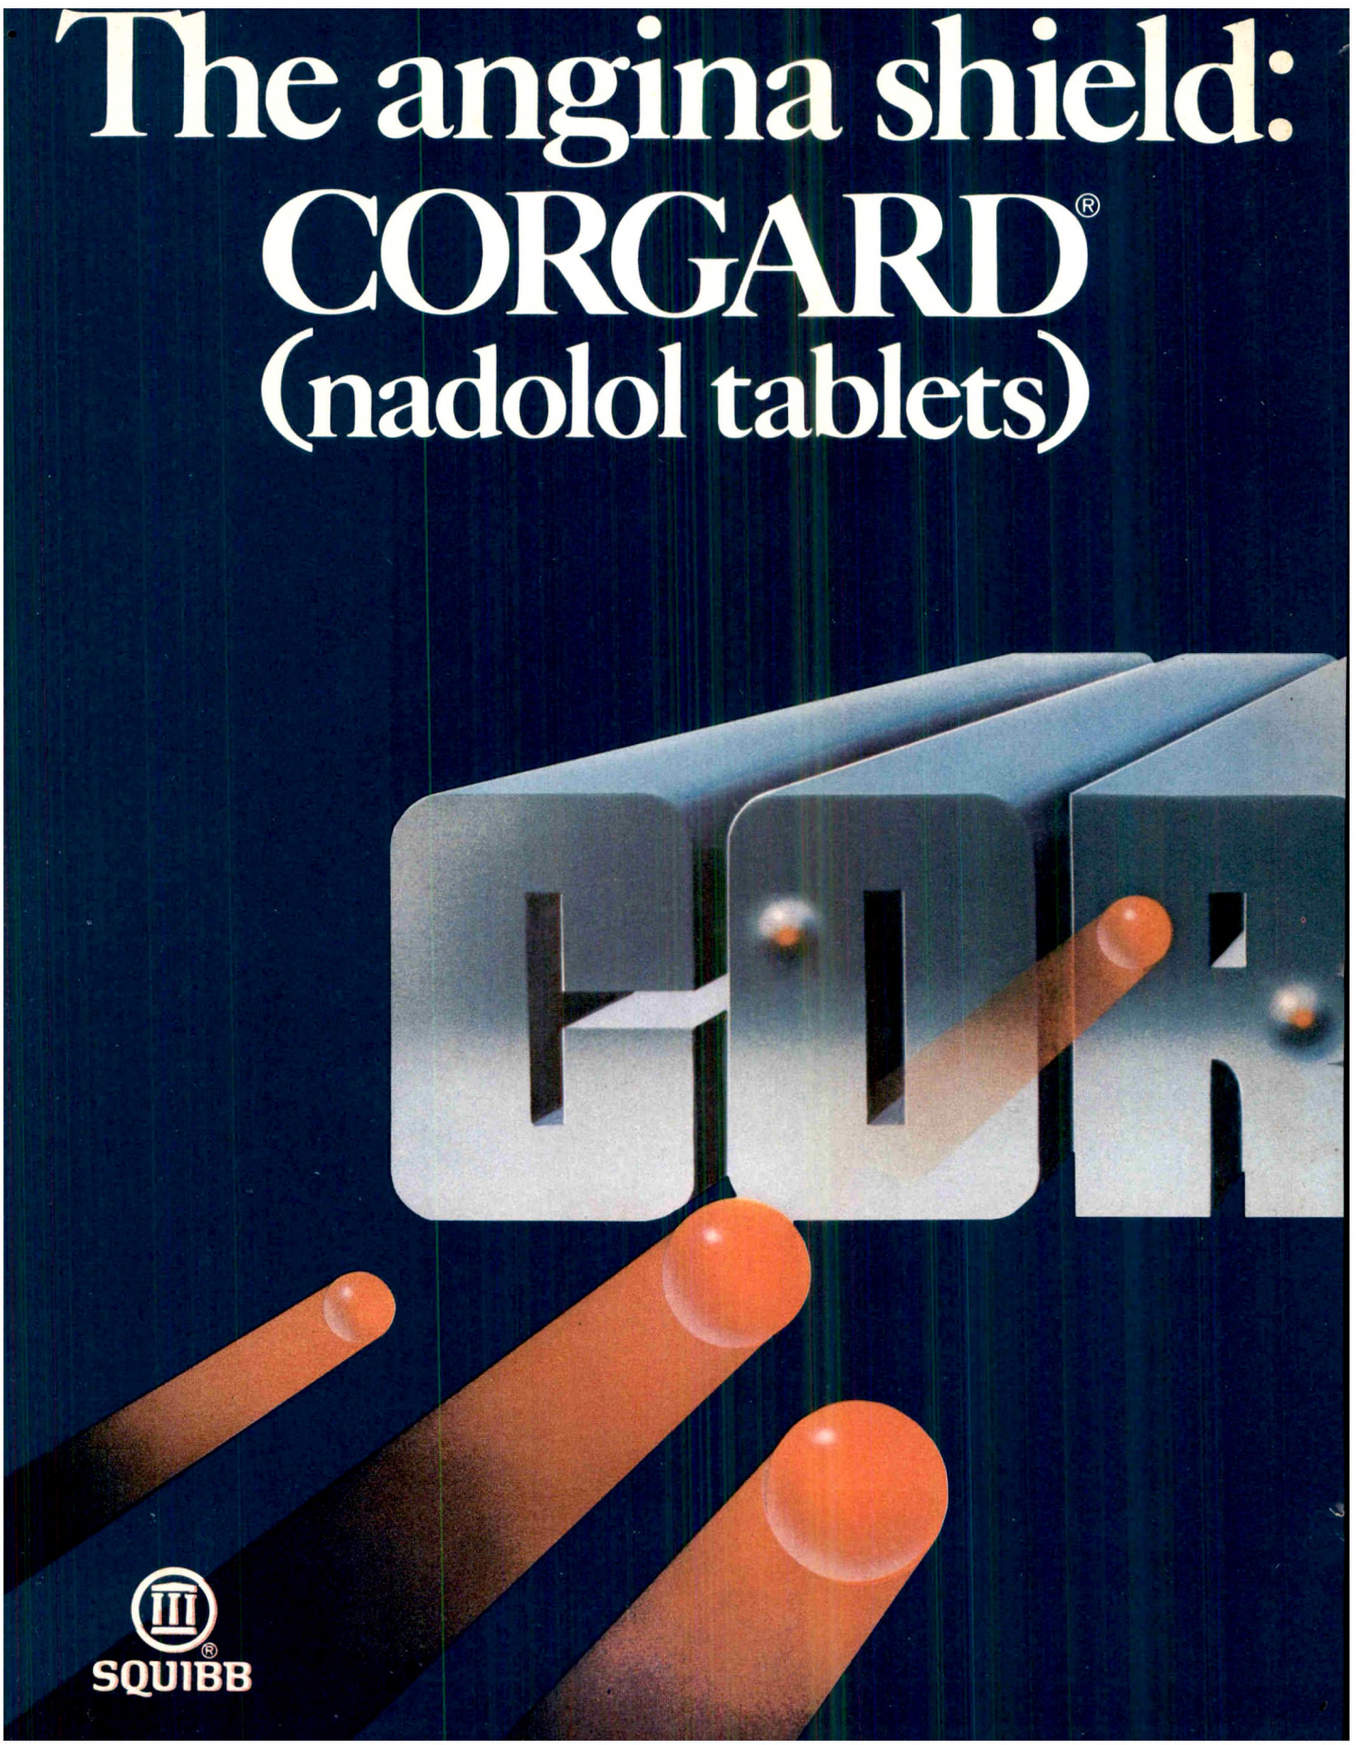
## CARDIOLOGIST

Needed to join an existing practice in a large multi-specialty clinic with co-located hospital on the West Coast of Florida. Excellent compensation and benefits. Send C.V. to: Box 225, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.



equal opportunity employer m/f

---



## FOR SALE

Ekoline 20A M-Mode echocardiographic unit. Contact GREG WALKER, Good Samaritan Hospital, West Palm Beach, Fla., 305-655-5511.

# The angina onslaught

# The angina shield:
# CORGARD®
# (nadolol tablets)

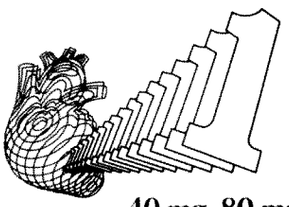
SQUIBB®

# Reliable 24-hour-a-day protection...

Physical exertion, emotional strain, and the unexpected crises of daily life — these can unleash an anginal attack at any time. So it's important to be certain that your patients are protected continuously. Unlike other beta-blockers, Corgard provides this protection around the clock with a once-daily dose — reducing the anginal attack rate, increasing work capacity, and decreasing the dependence on nitroglycerin.

# with convenient once-a-day dosage

A single daily dose of Corgard controls angina all day, every day. And since Corgard is associated with a low incidence of side effects,* your patients can lead more comfortable lives. An added convenience of Corgard is that it can be taken at any time of day, regardless of meals, because its absorption is not affected by food.



*For a full discussion of CONTRAINDICATIONS, PRECAUTIONS, ADVERSE REACTIONS, and WARNINGS, including avoidance of abrupt withdrawal, please see brief summary on next page.

# CORGARD® (nadolol tablets)

## The only once-a-day beta-blocker for both angina pectoris and hypertension

*se see next page for brief summary.*

# The only once-a-day beta-blocker for both angina pectoris and hypertension

# CORGARD® (nadolol tablets)

**40 mg, 80 mg, 120 mg, and 160 mg scored tablets available in a variety of bottle sizes and in Convenience Packages of 40 mg and 80 mg tablets**

**CORGARD® TABLETS**
**Nadolol Tablets**

**DESCRIPTION:** Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

**CONTRAINDICATIONS:** Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

**WARNINGS: Cardiac Failure** — Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

**Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal** — Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

**Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)** — PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

**Major Surgery** — Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

**Diabetes and Hypoglycemia** — Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

**Thyrotoxicosis** — Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

**PRECAUTIONS: Impaired Hepatic or Renal Function** — Use nadolol with caution in presence of either of these conditions (see DOSAGE AND ADMINISTRATION section of package insert).

**Information for Patients** — Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign or symptom of impending failure.

**Drug Interactions** — Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. When treating patients with nadolol plus a catecholamine-depleting agent, carefully observe for evidence of hypotension and/or excessive bradycardia which may produce vertigo, syncope, or postural hypotension.

**Carcinogenesis, Mutagenesis, Impairment of Fertility** — In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

**Pregnancy** — In animal reproduction studies with nadolol, evidence of embryo- and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus.

**Nursing Mothers** — It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when nadolol is administered to a nursing woman. Animal studies showed that nadolol is found in the milk of lactating rats.

**Pediatric Use** — Safety and effectiveness in children have not been established.

**ADVERSE REACTIONS:** Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

**Cardiovascular** — Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System** — Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory** — Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal** — Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating, and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous** — Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision. Although relationship to drug usage is not clear, sleep disturbances have been reported. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

**Potential Adverse Effects:** Although other adverse effects reported with other beta-adrenergic blocking agents have not been reported with nadolol, they should be considered potential adverse effects of nadolol. **Central Nervous System** — reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal** — mesenteric arterial thrombosis; ischemic colitis. **Hematologic** — agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic** — fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous** — reversible alopecia; Peyronie's disease; erythematous rash.

**OVERDOSAGE:** Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

**Excessive Bradycardia** — Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

**Cardiac Failure** — Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

**Hypotension** — Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

**Bronchospasm** — Administer a $beta_2$-stimulating agent and/or a theophylline derivative.

**DOSAGE:** For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 80 to 240 mg q.d. (most patients respond to 160 mg or less daily). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 80 to 320 mg q.d. (rarely, doses up to 640 mg may be needed).

Patients with renal failure require adjustment in dosing interval; see package insert for dosage in these patients.

For full prescribing information, consult package insert.

**HOW SUPPLIED:** In scored tablets containing 40, 80, 120, or 160 mg nadolol per tablet in bottles of 100 and 1000 tablets and in Unimatic® unit-dose packs of 100 tablets. The 40 mg and 80 mg tablets are also available in convenience packages containing 4 blister cards of 7 tablets each.

# Failure of Dobutamine to Increase Exercise Capacity Despite Hemodynamic Improvement in Severe Chronic Heart Failure

CAROL S. MASKIN, MD, ROBERT FORMAN, MD, EDMUND H. SONNENBLICK, MD, WILLIAM H. FRISHMAN, MD, and THIERRY H. LeJEMTEL, MD

**The acute hemodynamic and metabolic effects of dobutamine administered during exercise were studied in 8 patients with severe chronic heart failure. Exercise was performed on an upright bicycle ergometer using a graded protocol. During exercise performed without administration of dobutamine, exhaustion occurred after 4.5 ± 1.2 minutes of exercise. The cardiac index increased from 1.61 ± 0.25 to 2.67 ± 0.59 liters/min/m$^2$ ($p < 0.001$), the arteriovenous oxygen difference from 7.8 ± 1.7 to 12.5 ± 2.4 ml/100 ml ($p < 0.001$), and oxygen uptake from 7.9 ± 3.0 to 41.2 ± 15.7 mg/100 ml ($p < 0.001$). During exercise performed with the administration of dobutamine, the cardiac index was significantly greater than during the control state, 3.23 ± 0.78 versus 2.67 ± 0.59 liters/min/m$^2$ ($p < 0.001$), while the arteriovenous oxygen difference was significantly lower, 11.2 ± 2.1 vs 12.5 ± 2.4 ml/100 ml ($p < 0.01$). The arterial lactate level was not significantly changed, 45.3 ± 17.6 versus 41.2 ± 15.7 mg/100 ml. Although the dobutamine level tended to increase maximal oxygen uptake compared with the control period of exercise, 9.1 ± 1.2 versus 8.5 ± 1.4 ml/kg/min ($p < 0.05$), it did not significantly increase exercise capacity, 4.8 ± 1.5 versus 4.5 ± 1.2 min. Thus administration of dobutamine in patients with severe chronic heart failure increased the cardiac index during maximal exercise but failed to increase exercise capacity. Since arteriovenous oxygen difference is reduced, dobutamine probably increases blood flow to the nonexercising tissues and not to the actively metabolizing muscles.**

In patients with severe congestive heart failure, there is an inadequate increase in cardiac output during exercise which limits maximal oxygen uptake and exercise capacity.[1–3] When these patients are treated acutely with vasodilators, a higher cardiac output is reached at the point of exhaustion, but an increase in maximal oxygen uptake or exercise capacity does not occur.[4–7] Indeed, the increase in cardiac output produced by vasodilators is accompanied by a concomitant reduction in arteriovenous oxygen difference, which probably reflects a shunting of blood to organs other than exercising muscles.[8]

The effects of an acute inotropic intervention on exercise capacity and maximal oxygen uptake have not been thoroughly investigated. Although cardiac glycosides may increase cardiac output somewhat during exercise in the patient with heart failure,[9] the effects of this on exercise capacity and maximal oxygen uptake have not been studied. Recently the short-term administration of amrinone, a new nonglycosidic, nonadrenergic agent, has been shown to increase the capacity to perform exercise at a fixed work load.[10] However, whether inotropic therapy can acutely increase maximal oxygen uptake using a graded protocol is still unknown. Therefore, the effects of dobutamine, a synthesized catecholamine,[11] on exercise capacity and maximal oxygen uptake in patients with severe congestive heart failure were studied.

## Methods

**Patient population:** Seven men and 1 woman with severe chronic congestive heart failure were studied. The average patient age was 54.7 years (range 49 to 61). Three patients had ischemic heart disease as documented by coronary arteriography and prior myocardial infarction. Four had idiopathic cardiomyopathy, and one had persistent heart failure after successful mitral valve replacement. The mean duration of heart failure was 29 months (range 10 to 60). All were severely restricted in activity before elective hospital admission, 5

$AVO_2$ = arteriovenous oxygen difference; BSA = body surface area ($m^2$); CEx = control state exercise to exhaustion; CI = cardiac index; CR = control state at rest; HGB = hemoglobin (g/100 ml); HR = heart rate; MAP = mean arterial pressure; PCWP = pulmonary capillary wedge pressure; SVR = systemic vascular resistance; $VO_2$ = oxygen uptake; W = weight (kg).

being in New York Heart Association class IV and three in class III, despite optimal therapy with digitalis and diuretics. The mean digoxin level immediately before the study was 1.4 ± 0.5 mg/ml. Left ventricular ejection fraction, determined by gated radionuclide technique, averaged 23% (range 20 to 35). Sinus rhythm was present in all but 1 patient, who had atrial fibrillation. Patients were maintained on their usual doses of digoxin and furosemide, while nitrates, when taken, were discontinued 2 days before the study. No patient had had angina or a myocardial infarction within 3 months of the study. Studies were conducted in the coronary care unit. The nature, potential benefits, and possible risks of the study were fully explained to patients, who then gave written informed consent.

**Hemodynamics:** One day before the study, catheterization of the right side of the heart was performed in all patients using a triple-lumen flow-directed balloon-tipped thermodilution catheter (Edwards Laboratories), which was introduced percutaneously via a subclavian vein and advanced to a pulmonary wedge position by aid of fluoroscopy. On the day of the study, an intraarterial indwelling catheter was inserted percutaneously into a radial artery for measurement of systemic arterial pressure and for withdrawal of blood samples. Systemic arterial, pulmonary arterial, and pulmonary capillary wedge pressures were determined using Gould Statham P23ID transducers and recorded on an Electronics for Medicine photographic recorder. Heart rate was recorded continuously from a bedside electrocardiographic monitoring device. Cardiac output was determined in triplicate by thermodilution technique using iced 5% dextrose and a bedside computer (model 9250A), and confirmed by the Fick method using determination of oxygen consumption, and pulmonary artery and radial artery oxygen contents ($r = 0.96$, $n = 48$). Resting hemodynamic variables were measured with the patient sitting upright on the bicycle ergometer. The pressure transducers were positioned at the level of the fourth intercostal space. Two sets of similar resting determinations were obtained at intervals of 10 minutes. During the control period of exercise, pulmonary arterial pressure, mean systemic arterial pressure, and heart rate were monitored and measurements of cardiac output repeated continuously. At the end of each work load, as well as at the end of exercise, pulmonary capillary wedge pressure was measured. The following day, dobutamine was administered intravenously for 1 hour and the exercise protocol repeated to exhaustion. Hemodynamic measurements were performed as before. Derived hemodynamic values were calculated as follows: Cardiac index = cardiac output/body surface area (liters/min/$m^2$); Stroke volume index = cardiac index ×1,000/heart rate (ml/$m^2$); Systemic vascular resistance = mean arterial pressure/cardiac output (units).

**Oxygen uptake:** Measurements of mixed expired oxygen, mixed expired carbon dioxide, expired volume, expired gas temperature (°C), and barometric pressure were performed at rest while patients were sitting on the bicycle and every 30 seconds throughout exercise using a metabolic measurement cart (Beckman Instruments). Oxygen uptake (ml/kg/min) was calculated using standard formulas.[12] Patients were breathing through a mouthpiece and a low resistance, nonrebreathing, 3-way valve with a nose clamp. The oxygen analyzer (OM-11 Beckman Instruments) and carbon dioxide analyzer (LB-2 Beckman Instruments) were calibrated using an analyzed mixture of approximately 4% carbon dioxide and 16% oxygen in nitrogen. This calibration was made within 1 hour of the testing.

**Oxygen content and arterial lactate level:** All samples were evaluated in triplicate for oxygen content (volumes per unit) using a Lex-$O_2$ CON-TL oxygen analyzer (Lexington

Instruments). Multiple temperature and barometric pressure corrections were made throughout each study, and calibration of the Lex-$O_2$ CON-TL was considered optimal if 3 consecutive readings for dry air were within ±0.1 volume/100 ml. During the control period of exercise, systemic arterial ($SAO_2$) and pulmonary arterial ($PAO_2$) contents were measured at rest, at the end of each work load, and at exhaustion. Measurements were similarly performed during exercise and while on dobutamine. Arteriovenous oxygen difference in ml/100 ml was calculated as $SAO_2 - PAO_2$.

Arterial lactate concentration was measured by the enzymatic spectrofluorometric technique and expressed as mg/100 ml. Lactate determinations were made at the same times as oxygen contents.

**Exercise protocol:** Exercise testing was performed with the patient upright on an electronically braked bicycle ergometer (Warren E. Collins, Braintree, Massachusetts) with feet secured to the pedals. Two exercise tests were performed within 72 hours of the control period of exercise in the postabsorptive state and at least 4 hours after administration of furosemide, to determine reproducibility and to familiarize patients with the equipment. The initial work load was 25 W for 3 minutes. This load was increased every 3 minutes by 12.5 W until exhaustion. Patients pedaled at a frequency of at least 35 rpm. While receiving dobutamine, patients performed graded exercises in a similar fashion until exhaustion.

**Dobutamine administration:** After baseline determinations of hemodynamic function and systemic and pulmonary arterial oxygen contents in the supine position, dobutamine was infused at an initial rate of 5 μg/kg/min for 15 minutes. Measurements were repeated and the dose increased by 2 μg/kg/min every 5 minutes until maximal cardiac output was reached or adverse effects were elicited. Adverse effects were defined as a 10% increase in either heart rate or systolic arterial pressure above control values, or an increase in ventricular premature beats >5 beats/min above levels at rest. The optimal rate of infusion was defined as the value producing the largest increase in cardiac output without precipitating adverse effects. Dobutamine was then infused at the optimal dose level for 60 minutes. Resting hemodynamic and metabolic determinations were performed while patients were sitting on the bicycle, and the exercise protocol was then repeated.

**Statistical analysis:** The results are expressed as means ± standard deviations. Hemodynamic and metabolic changes were assessed using 2 factors within subjects analysis of variance model. Each patient was assessed at rest and at maximal exercise both before and during administration of dobutamine for a total of 4 observations.

Hemodynamic and metabolic variables were analyzed as a function of the effect of exercise (rest versus maximal exercise), the effect of the drug (control versus dobutamine administration), and the interaction of the 2 factors. In the presence of exercise-drug interactions, F tests were performed using orthogonal contrasts to determine the simple effects of the drug at maximal exercise.

## Results

While resting upright on the bicycle, the mean cardiac index averaged 1.61 ± 0.25 liters/min/$m^2$, and pulmonary capillary wedge pressure, 24.0 ± 10.5 mm Hg. Hemodynamic and metabolic variables are detailed in Table I. In the control state, exercise was sustained for 4.5 ± 1.2 minutes (Fig. 1), at which point the average cardiac index had increased to 2.67 ± 0.59 liters/min/$m^2$ ($p < 0.001$) and pulmonary capillary wedge pressure to 39.0 ± 8.9 mm Hg ($p < 0.001$). The limited increase in cardiac index during maximal exercise was due to a less than adequate increase in both heart rate, from 96.3 ± 14.1 to 131.8 ± 21.8 beats/min ($p < 0.001$), and stroke volume index, from 17.2 ± 4.7 to 20.9 ± 5.6 ml/$m^2$ ($p < 0.001$) (Fig. 2). At the point of exhaustion oxygen uptake had reached a plateau of 8.5 ± 1.4 ml/kg/min while the arteriovenous oxygen difference increased from 7.8 ± 1.7 at rest to 12.5 ± 2.4 ml/100 ml ($p < 0.001$) (Fig. 3). Blood lactate had increased from a control level of 7.9 ± 3.0 to 41.2 ± 15.7 mg/100 ml ($p < 0.001$) at the end of exercise.

Administration of dobutamine increased the resting cardiac index substantially in all patients from 1.61 ±

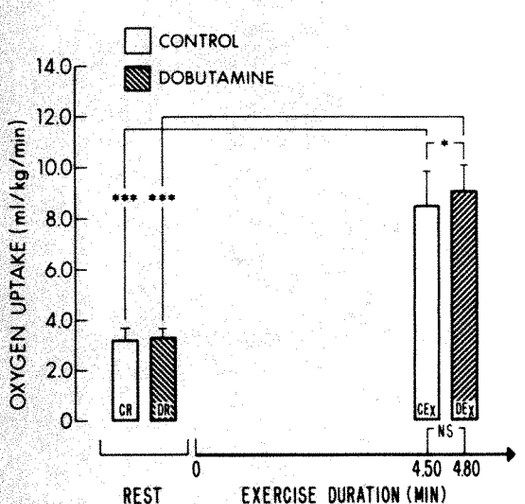

**FIGURE 1.** Oxygen uptake related to duration of exercise. At rest oxygen uptake is similar in the control period (CR) and during dobutamine administration (DR). The duration of exercise is not significantly different during the control period (CEx) and during dobutamine administration (DEx). Oxygen uptake is increased significantly during maximal exercise and tends to be slightly higher during administration of dobutamine than during the control period. NS = not significant. * $p < 0.01$; *** $p < 0.001$.

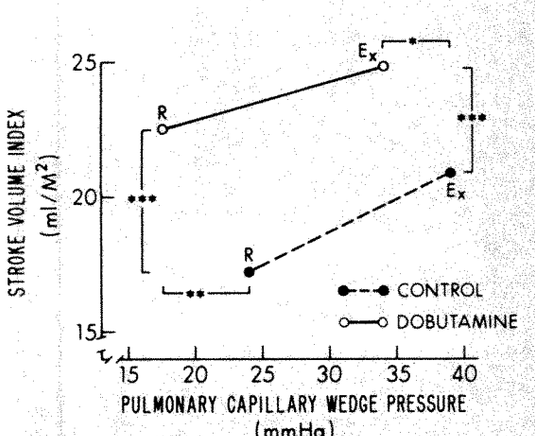

**FIGURE 2.** Relation between stroke volume index and pulmonary capillary wedge pressure during the control period of exercise and during exercise performed on dobutamine. Ex = exhaustion; R = rest. * $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$.

$AVO_2$ = arteriovenous oxygen difference; CI = cardiac index; DEx = dobutamine exercise to exhaustion; DR = dobutamine at rest; HR = heart rate; MAP = mean arterial pressure; PCWP = pulmonary capillary wedge pressure; SVR = systemic vascular resistance; $VO_2$ = oxygen consumption.

**FIGURE 3. Upper panel,** cardiac index at rest and at exhaustion during the control period and during exercise while the patient was receiving dobutamine. ** $p < 0.01$. **Middle panel,** arteriovenous oxygen difference at rest and exhaustion. ** $p < 0.01$; *** $p < 0.001$. **Lower panel,** oxygen uptake at rest and exhaustion. * $p < 0.05$.

0.25 to 2.17 ± 0.38 liters/min/m² ($p < 0.001$). Stroke volume index increased from 17.2 ± 4.7 to 22.5 ± 6.7 ml/m² ($p < 0.001$), while pulmonary capillary wedge pressure decreased from 24 ± 10.5 to 17.5 ± 9.8 mm Hg ($p < 0.01$) (Fig. 2). The resting heart rate was increased slightly from 96.3 ± 14.1 to 101.0 ± 19.5 beats/min ($p < 0.05$) and mean arterial pressure decreased from 89.1 ± 19.7 to 80.8 ± 15.0 mm Hg ($p < 0.05$). Oxygen uptake at rest was unchanged by dobutamine, and the arteriovenous oxygen difference decreased from 7.8 ± 1.7 to 6.1 ± 1.1 ml/100 ml ($p < 0.001$) (Fig. 3).

The optimal rate of infusion of dobutamine averaged 7.8 μg/kg/min (range 5 to 12). In 4 patients (1, 2, 6, and 7), the rate of infusion was limited by an excessive increase in heart rate, while in 2 others (4 and 8) an augmentation in ventricular premature beats was the limiting factor. A maximal increase in cardiac output was obtained in the remaining 2 patients (3 and 5).

Dobutamine therapy did not increase the duration of exercise significantly compared with the control period: 4.8 ± 1.5 versus 4.5 ± 1.2 minutes. Thus although oxygen uptake reached a higher plateau during exercise performed on dobutamine, 9.1 ± 1.2 versus 8.5 ± 1.4 ml/kg/min ($p < 0.05$), the change was not clinically meaningful (Fig. 1). The increase in cardiac performance observed at rest while dobutamine was administered was maintained at maximal exercise (Fig. 2). The

stroke volume index was significantly higher and pulmonary capillary wedge pressure lower than during the control period of exercise: 24.8 ± 7.9 versus 20.9 ± 5.6 ml/m$^2$ ($p < 0.001$) and 34.1 ± 9.01 versus 39.0 ± 8.9 mm Hg ($p < 0.05$), respectively. In Table II, the hemodynamic and metabolic parameters are detailed for the 8 patients during exercise performed while receiving dobutamine. At the point of exhaustion, mean arterial pressure tended to be lower on dobutamine than during the control period of exercise 97.6 ± 21.3 versus 102.4 ± 25.7 mm Hg ($p < 0.05$), while the maximal heart rate was similar, 134.1 ± 22.5 versus 131.8 ± 21.8 beats/min (difference not significant [NS]). The arteriovenous oxygen difference was lower during exercise performed while on dobutamine than in the control state, 11.2 ± 2.1 versus 12.5 ± 2.4 mg/100 ml ($p < 0.01$). Nevertheless, blood lactate levels were similar in both states, 45.3 ± 17.6 versus 41.2 ± 15.7 mg/100 ml (NS).

## Discussion

The present study shows that the acute administration of dobutamine improves cardiac output not only at rest but also during maximal exercise in patients with severe heart failure. However, exercise capacity was not improved.

At rest, left ventricular function was substantially depressed in our patients as demonstrated by a very low cardiac index and an elevated pulmonary wedge pressure. During exercise, a markedly diminished cardiac reserve was evidenced by a maximal oxygen uptake, ≤10 ml/kg/min, which is compatible with functional class IV of the New York Heart Association.[13] In patients with severe heart failure, inadequate augmentation of cardiac output during exercise is due to both impaired heart rate response, which parallels the degree of left ventricular dysfunction,[14] and limited ability to increase stroke volume despite a further increase in ventricular filling pressure.[15,16] In addition, patients with chronic heart failure demonstrate an abnormal peripheral vascular response to exercise which further limits maximal oxygen uptake.[17] A limited vasodilator response in exercising muscles has been observed in such patients and attributed to an increase in sodium and water content of the arteriolar wall,[18,19] increased tissue pressures,[20] an abnormal level of vasoconstriction in active muscle secondary to an exaggerated sympathoadrenal response to exercise,[21] or a combination of these. Furthermore, peripheral muscles of patients with heart failure may be unable to extract oxygen maximally due to metabolic and ultrastructural changes produced by prolonged physical inactivity.[22,23]

The rationale for the use of inotropic agents in the treatment of heart failure is to mobilize residual myocardial contractile reserve and thereby improve cardiac performance both at rest and during exercise. In the failing heart, the presence of contractile reserve has been demonstrated by the phenomenon of postextrasystolic potentiation[24] as utilized in paired stimulation.[25] However, whether inotropic agents can substantially augment cardiac performance and effect improvement in functional capacity is still controversial in patients with severe heart failure.[26]

Although cardiac glycosides increase myocardial contractility in patients with heart failure,[27] variable effects on cardiac performance at rest have been observed.[9,28–36] Differing responses to digitalis therapy in myocardial disease may be related to the natural course of congestive heart failure and the severity of disease. At an early stage, when cardiomegaly is present without circulatory failure, the increased myocardial contractility produced by digitalis may offer little or no change in already normal resting cardiac output and ventricular filling pressure.[29,31,32] Indeed, cardiac output may actually decrease if the peripheral effects of glycosides augment peripheral resistance.[32] When the disease process is more advanced and clinical evidence of congestive heart failure is present, the increase in myocardial contractility produced by digitalis tends to improve cardiac performance.[9,28,33,34] During terminal stages of the disease, a similar increase in myocardial contractility may no longer be sufficient to improve cardiac performance in the presence of an excessive increase in afterload.[35,36] A beneficial effect of digitalis therapy on maximal oxygen uptake has yet to be demonstrated.

Catecholamines, and especially dobutamine, increase myocardial contractility and improve resting hemodynamics in patients with heart failure.[37–41] Dobutamine augments myocardial contractility by direct stimulation of myocardial beta-1 receptors, resulting in increased levels of intracellular cyclic AMP.[42] In patients with heart failure the amount of cyclic AMP generated after incubation of lymphocytes with isoproterenol has been shown to be lower than in normal subjects.[43] Whether myocardial beta-1 receptors are similarly altered and whether such alteration limits myocardial responsiveness to beta-1 stimulation is not yet known.

Dobutamine also stimulates beta-2 adrenoreceptors, which mediate vasodilatation in the peripheral vessels.[11] This nonspecific vasodilatation induced by dobutamine may have contributed to the increased cardiac output in our patients both at rest and during exercise. However, since our patients were unable to exercise longer, the circulation to the exercising muscles probably did not benefit from the increased cardiac output. This observation may be explained by the following reasoning. In humans vascular beta-2 adrenoreceptors are located in the precapillary sphincters,[44] and the site of beta-adrenergic stimulation is different from the site of nerve-mediated vasoconstriction.[45] During maximal exercise the local release of metabolites in active muscles completely dilates precapillary sphincters,[46] while neurally released norepinephrine does not stimulate beta-2 adrenoreceptors.[47,48] Thus stimulation of beta-2 adrenoreceptors by dobutamine cannot further increase vasodilatation and blood flow to exercising muscles. In contrast, precapillary sphincters in the mesenteric bed are not exposed to local metabolites during exercise and can therefore be dilated by administration of dobutamine. Consequently, mesenteric blood flow is increased by dobutamine at rest[49] and probably during exercise. This increase in blood flow to tissues metabolically less active than the exercising muscles would explain the decrease in systemic arteriovenous oxygen difference

noted in patients receiving dobutamine. Although not fully understood, a similar phenomenon has been observed in patients with heart failure after administration of vasodilating agents.[4,6,7,50]

In patients with heart failure both dyspnea, which is related in part to an excessive increase in left ventricular diastolic pressure, and fatigue, which is due to a limited increase in cardiac output, are thought to limit exercise. Our patients receiving dobutamine were unable to exercise longer despite a higher cardiac output and lower ventricular diastolic pressure. This suggests that the factor limiting exercise was not the elevated diastolic filling pressure but rather inadequate oxygen delivery and peripheral accumulation of metabolites, probably lactate, in the exercising muscles.[51] Although lactate concentrations in muscle were not measured in this study, blood lactate levels at the point of exhaustion were similar whether dobutamine was being infused or not. Lower blood lactate levels might have been anticipated during dobutamine infusion since the cardiac output was higher while the level of exercise was comparable to that of the control state. However, administration of dobutamine may have increased lactate production in the exercising muscles.[52]

# Quantitative Differences in the Hemodynamic Effects of Captopril and Nitroprusside in Severe Chronic Heart Failure

MILTON PACKER, MD, JOSE MELLER, MD, NORMA MEDINA, RN, and MADELINE YUSHAK, RN

**The hemodynamic effects of oral captopril and intravenous nitroprusside were compared in 15 patients with severe chronic congestive heart failure. At doses of both drugs titrated so as to produce similar decreases in systemic vascular resistance in each patient, nitroprusside produced substantially greater increases in cardiac index (+0.67 versus +0.31 liters/min/m$^2$, p <0.01) but smaller decreases in mean arterial pressure (−18.4 versus −11.0 mm Hg, p <0.01) than did captopril. This finding was due to a significant decrease in heart rate with captopril (−7 beats/min, p <0.01) which was not seen with nitroprusside, since changes in stroke volume index with both drugs were similar. Nitroprusside produced a decrease in pulmonary arteriolar resistance quantitatively similar to the decrease in systemic vascular resistance, but the decrease in pulmonary arteriolar resistance with captopril was not significant. Despite similar decreases in systemic resistance, captopril produced a greater decrease in left ventricular filling pressure (−10.2 versus −6.9 mm Hg, p <0.01) but a smaller decrease in mean right atrial pressure (−3.1 versus −5.3 mm Hg, p <0.01) than did nitroprusside.**

**Thus, captopril has actions independent of its systemic vasodilator effects which account for the quantitative differences observed in its hemodynamic responses compared with those of nitroprusside in patients with severe chronic heart failure. These differences support experimental evidence that angiotensin, in addition to its direct systemic arterial vasoconstrictor actions, exerts positive chronotropic effects and alters ventricular compliance but has minimal direct effects on the limb venous circulation and on the pulmonary vasculature.**

All vasodilator drugs used in the management of patients with severe chronic heart failure are thought to exert their beneficial hemodynamic and clinical effects by acting on the peripheral circulation and thereby altering the loadings conditions that modulate cardiac performance.[1] Although these drugs may also directly improve myocardial contractility, coronary blood flow, or ventricular compliance,[2–7] it is difficult to determine to what extent such effects contribute to the hemodynamic changes caused by their use in humans. This is largely because changes in ventricular performance produced by changes in loading conditions are qualitatively similar to those that might be expected to result from an improvement in contractility or compliance.

Captopril is an orally effective inhibitor of the angiotensin-converting enzyme[8] which produces substantial hemodynamic and clinical improvement in patients with severe chronic heart failure.[9–13] It differs from direct-acting vasodilator drugs in that it exerts its effects not by a direct agonist action on the peripheral vasculature, but by inhibiting the circulatory responses to the endogenous vasoconstrictor angiotensin.[1,8] Because its administration is accompanied by both increases in cardiac output and decreases in ventricular filling pressure, captopril has been thought by many investigators to produce balanced vasodilation of peripheral arteries and veins in a fashion similar to nitroprusside.[14] Limb plethysmographic studies, however, have failed to confirm that captopril has important effects on the limb peripheral circulation in patients with heart failure.[15] This suggests that captopril improves cardiac performance by acting on regional circulations other than those in the extremities[15] or through mechanisms that do not involve systemic vasodilation.[2]

We sought to investigate this hypothesis by comparing the central hemodynamic effects of captopril with those of nitroprusside in patients with severe heart failure. The differences we observed in the responses to these 2 drugs suggest that captopril exerts some of its effects by mechanisms independent of its vasodilator actions.

## Methods

**Patient population:** We evaluated 15 patients with severe chronic heart failure who had persistent dyspnea, fatigue, or both at rest or on minimal exertion despite optimal conventional therapy with digitalis and diuretic agents. They included 9 men and 6 women aged 29 to 83 years (mean 66). The cause of heart failure was ischemic cardiomyopathy in 6 patients, idiopathic or alcoholic cardiomyopathy in 8 patients,

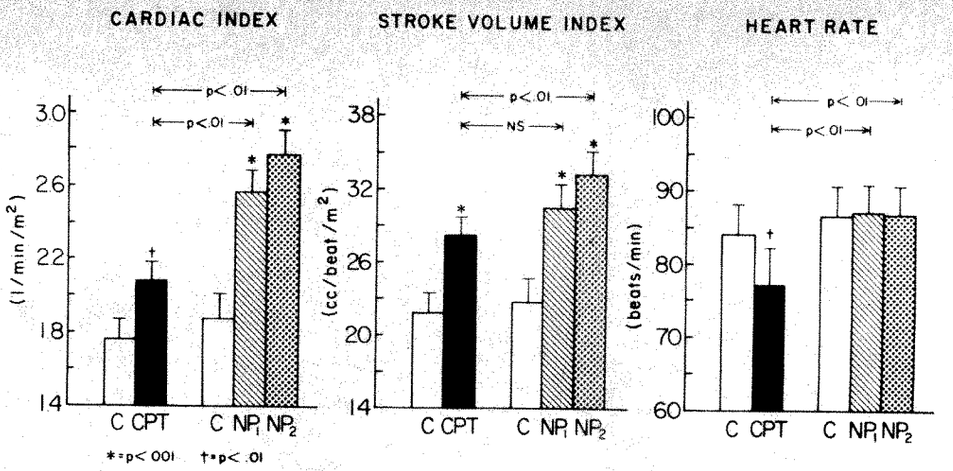

**FIGURE 1.** Changes in cardiac index, stroke volume index, and heart rate with captopril (CPT) and nitroprusside (NP), the latter titrated to 2 dose levels: $NP_1$, doses (104 μg/min) which produced captopril-like decreases in systemic vascular resistance, and $NP_2$, doses (180 μg/min) which produced captopril-like decreases in left ventricular filling pressure. All values are expressed as mean ± standard error of the mean. **Asterisks** and **daggers** represent significance of changes with each drug compared to its control values. P values above the bars represent significance of the hemodynamic changes with captopril compared with those produced by nitroprusside. C = control; NS = not significant.

and primary aortic valvular regurgitation with advanced ventricular dysfunction in 1 patient. The duration of heart failure was 11 months to 10 years. Normal sinus rhythm was present in 10 patients, atrial fibrillation in 4, and a ventricular pacemaker rhythm in 1.

**Hemodynamic measurements:** All patients were studied during a period of relative clinical stability. Bed rest was maintained, and all medications were withheld for 12 hours before evaluation. After written informed consent was obtained, right heart catheterization was performed with a triple-lumen flow-directed catheter for measurement of right atrial, pulmonary arterial, and pulmonary capillary wedge pressures. Arterial cannulas were inserted into the radial artery of all patients for measurement of systemic pressures. Measurements were made with zero reference level at the mid-axillary line with the patient in a supine position. Left ventricular filling pressure was measured as the mean pulmonary capillary wedge pressure. Thermodilution cardiac outputs were determined in triplicate by a bedside cardiac output computer with the use of iced injectate. Heart rates were derived from a continuously recorded electrocardiogram.

**Drug administration:** A protocol was designed to compare oral captopril with an intravenous infusion of nitroprusside titrated so as to achieve a similar reduction in systemic vascular resistance and left ventricular filling pressure in each patient under similar baseline hemodynamic conditions. Baseline determinations of the following variables were made repeatedly over 1 to 2 hours (with a variation <10%) before any drug intervention to ensure stability of the hemodynamic state: mean arterial pressure, heart rate, left ventricular filling pressure, mean pulmonary artery pressure, mean right atrial pressure, and cardiac output.

Each patient received both nitroprusside and captopril. Nine patients received nitroprusside first and captopril thereafter; the order was reversed in the other 6 patients. The administrations of the 2 drugs were separated by at least 24 hours.

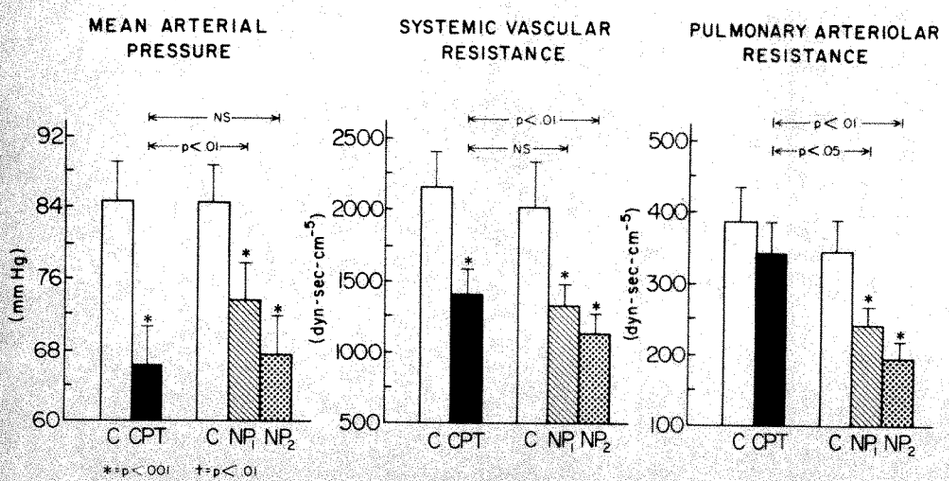

**FIGURE 2.** Changes in mean arterial pressure, systemic vascular resistance, and pulmonary arteriolar resistance with captopril (CPT) and nitroprusside (NP). Format and abbreviations as in Figure 1.

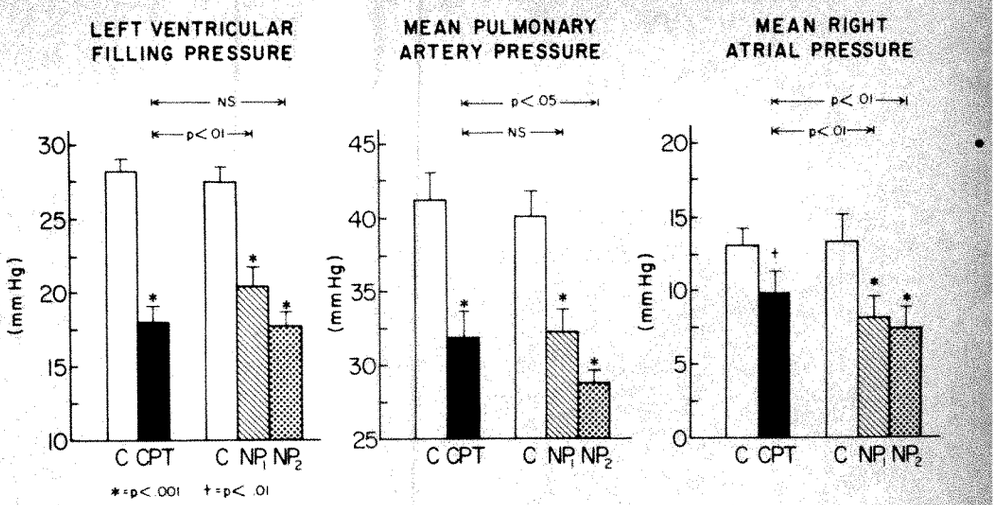

**FIGURE 3.** Changes in left ventricular filling pressure, mean pulmonary artery pressure, and mean right atrial pressure with captopril (CPT) and nitroprusside (NP). Format and abbreviations as in Figure 1.

Sodium nitroprusside was administered in a fashion similar to that previously described.[16] Briefly, 50 mg of the drug (Nipride®) was reconstituted in 250 ml of 5% dextrose in water and infused by peripheral vein at controlled rates determined by an IVAC 530 infusion pump apparatus. The infusion rate was initially 16 μg/min and was increased to 33, 67, 107, 213, and 330 μg/min with increments every 30 minutes; all hemodynamic variables were redetermined 20 minutes after each increment in the nitroprusside infusion. After the maximal dose of nitroprusside was infused, the drug was discontinued and hemodynamic variables were permitted to return to control values.

Captopril was administered as 25 mg orally. This dose was chosen because of its established effectiveness in previous evaluations of this agent.[9,11-13] After captopril administration, all hemodynamic variables were redetermined at 30-minute intervals for 3 hours.

**Data analysis:** Mean systemic and pulmonary artery pressures were determined by electronic filtration. Derived hemodynamic variables were calculated as follows: cardiac index (CI) = CO/body surface area (liter/min/$m^2$); stroke volume index (SVI) = CI/HR (ml/beat/$m^2$); systemic vascular resistance (SVR) = 80 × (MAP − MRAP)/CO (dynes s $cm^{-5}$); pulmonary arteriolar resistance (PAR) = 80 × (MPAP − LVFP)/CO (dynes s $cm^{-5}$), where CO denotes cardiac output, HR = heart rate, MAP = mean arterial pressure, MRAP = mean right atrial pressure, MPAP = mean pulmonary artery pressure, and LVFP = left ventricular filling pressure.

The hemodynamic responses at the time of maximal captopril effect (30 to 120 minutes after drug administration) were noted. The range of infused rates of nitroprusside was then examined retrospectively and 2 doses were selected for comparative analysis: (1) the dose of nitroprusside which produced a percent reduction in systemic vascular resistance in each patient of magnitude similar to that produced by captopril ($NP_1$), and (2) the dose of nitroprusside which produced a reduction in left ventricular filling pressure in each patient of magnitude similar to that produced by captopril ($NP_2$). The hemodynamic effects of each drug were compared to their respective control values by the *t* test for paired data. The magnitude of the hemodynamic responses to captopril and to both dose levels of nitroprusside were compared by analysis of variance; Duncan's multiple range test was used to differentiate among mean responses.[17] Group data are expressed as mean ± standard error of the mean.

## Results

The control hemodynamic variables before the administration of captopril and nitroprusside were similar. With both drugs, cardiac and stroke volume indexes increased in association with decreases in right and left ventricular filling pressures, in mean systemic and pulmonary arterial pressures, and in systemic vascular resistance ($p < 0.01$ or $p < 0.001$ for all variables). The hemodynamic responses to the administration of each drug are shown in Figures 1 to 3.

**Comparative responses at matched reductions in systemic resistance:** The doses of nitroprusside which produced decreases in systemic vascular resistance similar to those observed with captopril in each patient ranged from 16 to 330 μg/min (mean 104 ± 27). At this dose, nitroprusside produced substantial decreases in pulmonary arteriolar resistance as well ($p < 0.001$) and the magnitude of this effect was similar to that observed in the systemic circulation (−30 versus −34%, respectively). In contrast, captopril produced no significant decreases in pulmonary arteriolar resistance (−11%, $p > 0.10$), and the magnitude of the decrease in vascular resistance in the systemic circuit with captopril in each patient always exceeded that observed in the pulmonary circulation. The effects of nitroprusside and captopril on pulmonary arteriolar resistance differed significantly, $p < 0.01$.

Despite similar decreases in systemic vascular resistance with both drugs, nitroprusside produced significantly greater increases in cardiac index (+0.69 versus +0.31 liters/min/$m^2$, $p < 0.01$) and smaller decreases in mean arterial pressure (−11.0 versus −18.4 mm Hg, $p < 0.01$) than captopril. The smaller increase in cardiac index with captopril was associated with a decrease in heart rate (−7 beats/min, $p < 0.01$), whereas no significant changes in heart rate were observed with nitroprusside. Changes in stroke volume index with both drugs were similar (+7.9 ml/beat/$m^2$ with nitroprusside and +6.3 ml/beat/$m^2$ with captopril).

Despite similar decreases in systemic vascular resistance with both drugs, captopril produced substantially

greater decreases in left ventricular filling pressure (−10.2 mm Hg versus −6.9 mm Hg, $p < 0.01$) but significantly smaller decreases in mean right atrial pressure (−3.1 mm Hg versus −5.3 mm Hg, $p < 0.01$) than did nitroprusside. Changes in mean pulmonary artery pressure with both drugs were similar (−9.3 mm Hg with captopril and −8.0 mm Hg with nitroprusside).

**Comparative responses at matched reductions in left heart filling pressures:** The doses of nitroprusside which produced decreases in left ventricular filling pressures similar to those observed with captopril in each patient ranged from 67 to 330 μg/min (mean 180 ± 43), a dose significantly larger than that needed to produce captopril-like decreases in systemic vascular resistance ($p < 0.01$). As a result, these larger doses of nitroprusside produced significantly greater decreases in systemic vascular resistance than did captopril (−44 versus −34%, $p < 0.01$).

Despite this greater decrease in systemic resistance with nitroprusside, mean arterial pressure decreases similarly with both drugs; this reflected the substantially smaller increase in cardiac index with captopril than was seen with nitroprusside (+0.31 versus +0.90 liters/min/$m^2$, $p < 0.01$). The different effects on cardiac index were the result of both a decrease in heart rate seen with captopril (but not seen with nitroprusside) and a greater increase in stroke volume index with this higher dose of nitroprusside than was seen with captopril (+10.5 versus +6.3 ml/beat/$m^2$, respectively, $p < 0.01$).

Although (with these larger doses of nitroprusside) left ventricular filling pressure decreased similarly with both drugs, nitroprusside produced significantly greater decreases in mean right atrial pressure (−5.9 versus −3.1, $p < 0.01$) and in mean pulmonary artery pressure (−11.6 versus 9.3 mm Hg, $p < 0.01$) than did captopril.

## Discussion

The hemodynamic responses to captopril in our patients with severe chronic heart failure differed from those observed with nitroprusside with respect to 3 variables: (1) heart rate, (2) pulmonary arteriolar resistance, and (3) right and left ventricular filling pressures.

**Effects of captopril on heart rate:** Heart rate decreased significantly with captopril in our patients but did not change after the administration of nitroprusside. Hence, when doses of both drugs were matched so as to produce similar decreases in systemic vascular resistance, cardiac index increased less and mean arterial pressure decreased more with captopril than with nitroprusside. Although decreases in heart rate have been noted by other investigators after captopril administration to patients with heart failure,[11,13] such changes might have been a nonspecific effect of therapy, since heart rate frequently slows after the administration of any vasodilator drug that improves cardiac performance, and thereby leads to a withdrawal of reflex adrenergic activity.[18,19] In the present study, captopril and nitroprusside both produced marked improvements in stroke volume and left ventricular filling pressure, but a decrease in heart rate was observed only with captopril, and thus, must have been the consequence of a negative chronotropic effect of the drug independent of its peripheral vasodilator actions. Such effects are likely mediated by inhibition of the direct cardioaccelerating effects of angiotensin.[20,21]

When captopril is administered to hypertensive patients, the negative chronotropic effects of the drug are offset by baroreceptor-mediated reflex tachycardia, and thus little change in heart rate is observed.[22] In contrast, in patients with heart failure, autonomic reflexes are attenuated,[23] and thus the negative chronotropic actions of captopril are left unopposed and heart rate slows. A similar explanation has been proposed to account for the responses seen with the peripheral vasodilator drug, prazosin, which directly slows the sinus node.[24] Like captopril, prazosin produces no change in heart rate in hypertensive patients but may decrease heart rate in patients with heart failure; in doing so, prazosin produces relative changes in cardiac index, mean arterial pressure, and systemic vascular resistance similar to those observed in the present study with captopril.[16]

**Effects of captopril on pulmonary arteriolar resistance:** Captopril exerted minimal effects on pulmonary arteriolar resistance and right heart filling pressures in our patients with severe heart failure. This is consistent with experimental evidence that angiotensin has no direct effects on the pulmonary vasculature or the limb venous circulation,[25–28] and with clinical evidence that angiotensin inhibition produces little change in pulmonary vascular resistance[12,15,29–31] or systemic limb venous capacitance.[15,29] It is likely that both of these factors contribute to the modest decreases in mean right atrial pressure we observed with captopril, since right ventricular filling pressures are determined both by systemic venous return and by the impedance to right ventricular ejection. Accordingly, because of its marked effects on systemic limb venous capacitance and on pulmonary arteriolar resistance,[14] nitroprusside produced greater decreases in mean right atrial pressure than did captopril. The minimal effects of captopril on pulmonary arteriolar resistance may explain why arterial oxygen content does not decrease in patients with heart failure after converting-enzyme inhibition[32] but does decrease significantly with drugs that possess direct pulmonary vasodilating actions (such as nitroprusside).[33]

**Effects of captopril on ventricular filling pressures:** Despite *smaller* decreases in right heart filling pressures, captopril produced *greater* decreases in left ventricular filling pressure than did nitroprusside. This was an unexpected finding. Since captopril exerts minimal effects on systemic venous capacitance and right heart filling pressures, we would have expected a smaller decrease in central blood volume (volume of the circulation from the pulmonary valve to the aortic valve[34]) and hence in pulmonary capillary wedge pressure with captopril than with nitroprusside at doses matched to produce similar decreases in systemic vascular resistance. Even if we attributed the more modest decreases in mean right atrial pressure with captopril

entirely to its lesser reduction of right ventricular afterload (thus assuming that decreases in central blood volume with both drugs were similar), we would have anticipated that left heart filling pressure would have decreased similarly with captopril and nitroprusside. Our observation, however, that left ventricular filling pressure decreased *more* with captopril suggests that this drug must act to lower left heart pressure by a mechanism independent of changes in the peripheral arterial or venous circulations, possibly by a direct effect on pulmonary vascular compliance or by changing the pressure-volume relations in the left ventricle.[2] The latter hypothesis is supported by the work of Alderman and Glantz,[5] who noted that angiotensin shifts the pressure-volume relations of the human left ventricle so as to make the ventricle less compliant; antagonism of this shift by captopril could contribute to the marked decrease in left ventricular filling pressure we observed.

**Limitations of the study:** We tried to explain the observed differences between the effects of captopril and nitroprusside in our patients with severe heart failure by attributing to captopril actions opposite of those characteristic of angiotensin. However, since we only measured a limited number of central hemodynamic variables, our hypotheses are based on several assumptions. Although both drugs were titrated to produce similar decreases in systemic vascular resistance, direct measurements of ventricular afterload (wall stress and aortic impedance[35,36]) were not performed; if these loading variables were affected differently by nitroprusside and captopril, this might have contributed to some of the differences we observed between them. We attributed observed differences in the effects of the 2 drugs on left heart filling pressure to hypothesized differences in their effects on ventricular compliance; yet, we did not measure ventricular volumes, and we assumed that the effects of nitroprusside were entirely attributable to peripheral vasodilation. However, nitroprusside may also alter ventricular pressure-volume relations, although such effects appear quantitatively less marked than those exerted by angiotensin.[5] Finally, we assumed that observed differences in the effects of the 2 drugs on heart rate were the result of a direct negative chronotropic effect of captopril, but since both drugs affected right and left ventricular filling pressures differently, differences in degree of reflex stimulation of intracardiac mechanoreceptors[37] might also have accounted for the observed heart rate responses; captopril-induced decreases in heart rate may also be secondary to its effects on the sympathetic nervous system.[38] Further work needs to be done to confirm by direct measurement the hypotheses suggested by our observations.

**Clinical implications:** The differences we observed in the circulatory effects of captopril and nitroprusside in our patients with severe heart failure have important clinical implications. Although captopril's negative chronotropic effects could be clinically beneficial in patients with underlying coronary artery disease, the decrease in heart rate could potentiate the profound hypotension that is occasionally seen with initial doses of the drug[11,12]; indeed, the decreases in mean arterial pressure with captopril in heart failure patients are greater than those observed with most other vasodilator agents. Furthermore, patients with sick sinus syndrome may experience severe symptomatic bradycardias with the use of antihypertensive agents that possess direct negative chronotropic effects,[39] and caution should be exercised in the use of captopril in these patients. Of 54 patients with severe chronic heart failure that we have treated with captopril, 2 manifested asymptomatic but recurrent episodes of severe sinus bradycardia (heart rates <40 beats/min), which were shown to be directly attributable to treatment with the drug by rechallenge studies. Both patients had a history compatible with sick sinus syndrome before institution of captopril therapy.

Our findings that captopril has minimal effects on pulmonary arteriolar resistance also has clinical importance. The lack of a significant pulmonary vasodilator action suggests that captopril has limited usefulness in patients with marked impairment of right ventricular function, whereas most other systemic vasodilator drugs used in the management of heart failure possess marked effects on the pulmonary vasculature and can improve right heart performance.[40] As a result, the use of captopril should probably be avoided in patients with severe pulmonary vascular disease, regardless of whether it is structurally fixed or due to active vasoconstriction. In such patients, the failure of captopril to reduce transpulmonary resistances is likely to limit any increases in cardiac output that might otherwise be expected to accompany drug-induced systemic vasodilation, and this might result in profound systemic hypotension. This hypothesis requires further study.

**Conclusion:** Our comparative study of the responses to captopril and nitroprusside in patients with severe heart failure indicates that captopril exerts hemodynamic effects independent of its systemic vasodilator actions. These effects are consistent with the concept that the responses to captopril are mediated by inhibition of angiotensin, which has direct arterial vasoconstrictive and positive chronotropic actions and alters ventricular compliance, but has minimal direct effects on the limb venous circulation and on the pulmonary vasculature.

**Acknowledgment:** We are indebted to the nurses of the Ames and Rose Cardiac Care Units of the Mount Sinai Medical Center for their invaluable help in the completion of this study; to Leonard G. Dennick, MD, of the Squibb Institute for Medical Research, Princeton, New Jersey, who generously provided supplies of captopril; and to Irma Rosenblatt for secretarial assistance.

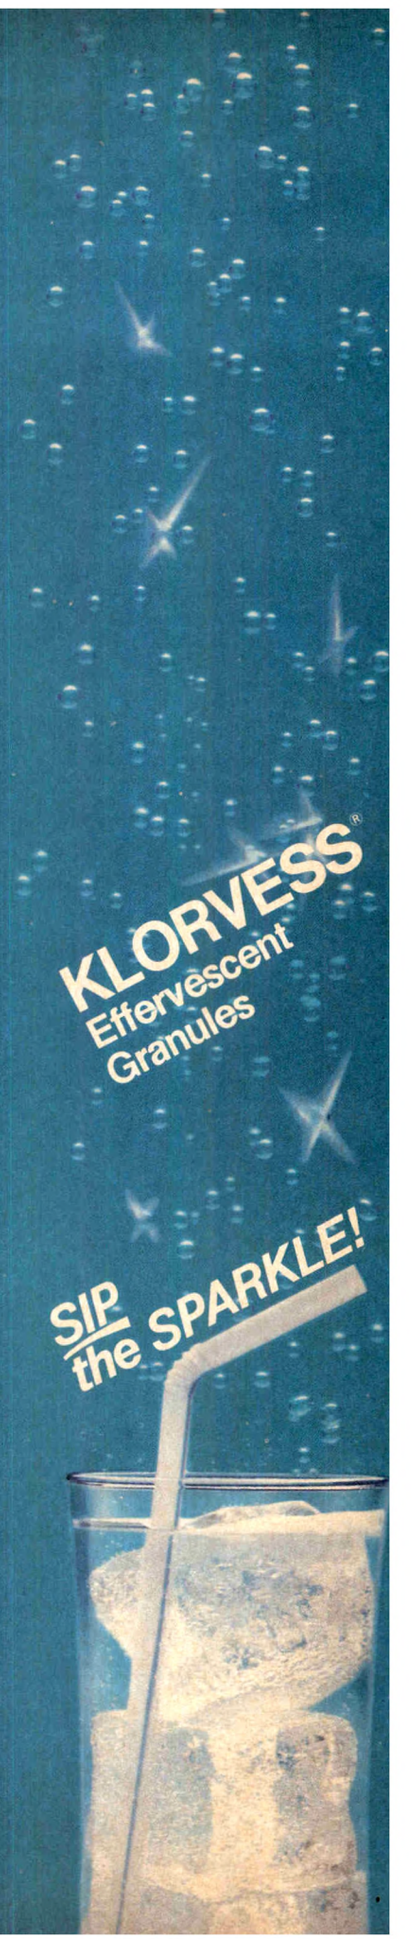
# When patients need more potassium than tablets can easily offer...

©1982 Sandoz, Inc.

# Consider the simplicity of KLORVESS® EFFERVESCENT GRANULES

Each packet (2.8 g) provides 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, and L-lysine monohydrochloride 0.913 g.



***The patient on higher doses of antihypertensive medication,*** diuretics and/or digitalis, may need additional potassium supplementation...40 mEq/day or more. KLORVESS Effervescent Granules offer the following advantages:

- ***Each packet delivers 20 mEq of potassium***...compared with slow-release tablets that contain 10 mEq or less.
- ***Sparkling citrus flavor offers a high degree of patient compliance.*** Patients may even use KLORVESS as a "chaser" for other medications. Granules mix easily with cold water...no need for expensive juices to make palatable.
- ***Convenient effervescent granules dissolve almost immediately***...no waiting.
- ***Sugar-free, sodium-free, carbohydrate-free, dye-free formulation***...ideal for hypertensive, diabetic, or overweight patients.

## Klorvess® Effervescent Granules and Klorvess® (potassium chloride) 10% Liquid

*Brief summary of prescribing information*

**DESCRIPTION:** *Klorvess Effervescent Granules:* Each packet (2.8 g) contains 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, L-lysine monohydrochloride 0.913 g in a sodium-, sugar- and carbohydrate-free effervescent formulation. Dissolution of the packet contents in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate and L-lysine monohydrochloride.

*Klorvess (potassium chloride) 10% Liquid:* Each tablespoonful (15 ml) contains 20 mEq of potassium chloride (provided by potassium chloride 1.5 g) in a palatable, cherry-with-pit flavored vehicle, alcohol 1%.

**INDICATIONS:** For the prevention and treatment of potassium depletion and hypokalemic-hypochloremic alkalosis. Deficits of body potassium and chloride can occur as a consequence of therapy with potent diuretic agents and adrenal corticosteroids.

**CONTRAINDICATIONS:** Severe renal impairment characterized by azotemia or oliguria, untreated Addison's disease, Familial Periodic Paralysis, acute dehydration, heat cramps, patients receiving aldosterone-inhibiting or potassium-sparing diuretic agents, or hyperkalemia from any cause.

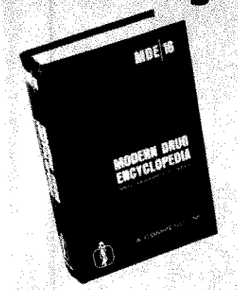
**PRECAUTIONS:** In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. In the presence of normal renal function and hydration, it is difficult to produce potassium intoxication by oral potassium salt supplements. Since the extent of potassium deficiency cannot be accurately determined, it is prudent to proceed cautiously in undertaking potassium replacement. Periodic evaluations of the patient's clinical status, serum electrolytes and the EKG should be carried out when replacement therapy is undertaken. This is particularly important in patients with cardiac disease and those patients receiving digitalis. High serum concentrations of potassium may cause death through cardiac depression, arrhythmia or cardiac arrest. To minimize gastrointestinal irritation associated with potassium chloride preparations, patients should dissolve the packet contents of *Klorvess Effervescent Granules* in 3 to 4 ounces of cold water, fruit juice or other liquid or dilute each tablespoonful of *Klorvess (potassium chloride) 10% Liquid* in 3 to 4 ounces of cold water. Both of these solutions should be ingested slowly with or immediately after meals.

**ADVERSE REACTIONS:** Abdominal discomfort, diarrhea, nausea and vomiting may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias, heaviness, muscle weakness and flaccid paralysis of the extremities. Potassium intoxication can produce listlessness, mental confusion, a fall in blood pressure, shock, cardiac arrhythmias, heart block and cardiac arrest. The EKG picture of hyperkalemia is characterized by the early appearance of tall, peaked T waves. The R wave is decreased in amplitude and the S wave deepens; the QRS complex widens progressively. The P wave widens and decreases in amplitude until it disappears. Occasionally, an apparent elevation of the RS-T junction and a cove plane RS-T segment and T wave will be noted in AVL.

**DOSAGE AND ADMINISTRATION:** *Klorvess Effervescent Granules:* Adults—One packet completely dissolved 2 to 4 times daily depending upon the requirements of the patient.

*Klorvess (potassium chloride) 10% Liquid:* Adults—One tablespoonful (15 ml) completely diluted in cold water 2 to 4 times daily depending upon the requirements of the patient.

Both of these solutions should be ingested slowly with meals or immediately after eating.



**OVERDOSAGE:** Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours. In digitalized patients too rapid a lowering of plasma potassium concentration can cause digitalis toxicity.

**HOW SUPPLIED:** *Klorvess Effervescent Granules*—packages of 30 packets (2.8 g each). *Klorvess (potassium chloride) 10% Liquid* (dark red)—as a cherry-with-pit flavored liquid in pint and gallon bottles. Klorvess Effervescent Granules and Liquid are also available in institutional packaging as follows: *Klorvess Effervescent Granules*—packages of 1000 packets; *Klorvess Liquid*—36 (3 x 12) x 4 oz Unit-of-Use bottles and 100 (4 x 25) x 15 ml Unit-Dose bottles.

# How thorough and unbiased is your drug reference?

## If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

### MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

**Arthur J. Lewis,** MD, Executive Editor
**Gertrude Dittus Gonzales,** R.Ph., B.S. Pharm., Executive Editor
**Charles L. Winek,** Ph.D., Contributing Editor

The all new 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

**Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:**

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

**The 1,000 page main section** arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

**Three a-z indexes provide** instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

# A Formula For Success
## (In 24 Hour Ambulatory ECG Monitoring)

Why did Marquette Electronics enter the already crowded Holter monitoring equipment business?

Simply because we are convinced that ambulatory ECG monitoring needed an entirely new approach to the problem, and that we could offer valuable new technology.

Actually, we do a number of things that are entirely new:

- We digitize all 24 hours of data from the patient's tape recording on a "megabyte" sized, hard disc so we have immediate access to every segment, every beat of the record without winding, rewinding and waiting to find events on the tape.
- We process this string of perhaps 100,000 cardiac beats through an "Array Processor", a new type of high speed computer. Of course, with everything immediately accessible on disc, it is possible to do *retrospective* analysis of the data rather than doing everything on the fly.
- We automatically generate a comprehensive, accurate summary of the patient's data, ready for physician/technician review in 15 minutes, but save all the data on disc until the overreading process is completed. In this way, any part of the 24-hour record can be examined, challenged and edited.
- We do all of this in multiple ECG lead format so that there's a much better chance of separating noise artifact from the real data and in calling ectopic beats accurately.
- And, we built a highly-automated manufacturing facility to produce an ambulatory pocket recorder that's smaller, lighter, more reliable and lower in cost than any competitive instrument on the market.

So, you see, there are lots of solid reasons why you should take a careful look at this new Marquette equipment before you buy a Holter System.

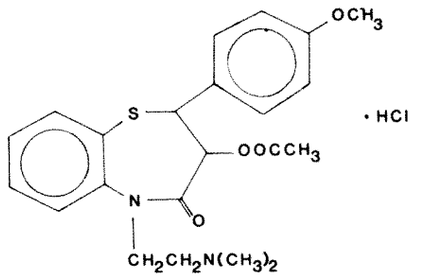
# Announcing NEW cardizem™ (diltiazem HCl)

## CALCIUM CHANNEL BLOCKADE FROM MARION LABORATORIES

Please see full prescribing information on next page.



# PROFESSIONAL USE INFORMATION

## cardizem™ (diltiazem HCl)

**30 mg and 60 mg tablets**

## DESCRIPTION

CARDIZEM™ (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy)-5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-,monohydrochloride,(+) -cis-. The chemical structure is:

Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem for oral administration.

## CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

**Mechanism of Action.** Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

**Hemodynamic and Electrophysiologic Effects.** Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate/blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

**Pharmacokinetics and Metabolism.** Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels 2 to 3 hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent as a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

## INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous coronary artery spasm presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents. CARDIZEM has been effective in short-term controlled trials in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness is incomplete.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

## CONTRAINDICATIONS

CARDIZEM is contraindicated in 1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, 2) patients with second- or third-degree AV block, and 3) patients with hypotension (less than 90 mm Hg systolic).

## WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (4 of 959 patients for 0.42%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** There has been a single report in a patient receiving 120 mg of diltiazem t.i.d. of marked transaminase elevation (SGOT 4500, SGPT 2300) accompanied by hyperbilirubinemia (to 3 mg%), occurring after four days of treatment. The enzyme abnormalities resolved entirely, and enzymes were nearly normal a week after cessation of treatment. No rechallenge was carried out, but the patient had no evidence of viral hepatitis and received no other drugs but isosorbide dinitrate.

No other similar liver injury has been reported in clinical trials, but marketing experience in l resulted in a rechallenge confirmed instance of hepatocellular injury. However, it should be noted have been further episodes of raised transaminases in the absence of diltiazem in this patient, relationship to diltiazem of the abnormalities is not completely clear. Other instances of tra elevation have been reported in Europe, but their relationship to drug is uncertain.

## PRECAUTIONS

**General.** CARDIZEM is extensively metabolized by the liver and excreted by the kidneys and in bile. A new drug given over prolonged periods, laboratory parameters should be monitored at regular interval should be used with caution in patients with impaired renal or hepatic function. In subacute and chron rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also with hepatic changes; however, these changes were reversible with continued dosing.

**Drug Interaction.** Pharmacologic studies indicate that there may be additive effects in prolonging AV when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS)

Uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities; the effect on serum digoxin levels has not been examined. The safety of the combination of CARDIZEM and beta-l digitalis is currently being investigated in well-controlled studies.

**Carcinogenesis, Mutagenesis, Impairment of Fertility.** A 24-month study in rats and a 21-month st showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial intrinsic effect on fertility was observed in rats.

**Pregnancy.** Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Adm of doses ranging from 5 to 10 times greater (on a mg/kg basis) than the daily recommended therapeuti resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cau abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup w survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant wor the potential benefit justifies the potential risk to the fetus.

**Nursing Mothers.** It is not known whether this drug is excreted in human milk. Because many excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if benefits are thought to outweigh its potential risks in this situation.

**Pediatric Use.** Safety and effectiveness in children have not been established.

## ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized th with impaired ventricular function and cardiac conduction abnormalities have usually been excluded. with an added beta-blocker is also extremely limited.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZE was not greater than that reported during placebo therapy.

In addition, the following have been reported infrequently and represent occurrences which can reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relat CARDIZEM has not been established. The most common occurrences, as well as their frequency of pre are nausea (2.7%), swelling/edema (2.4%), arrhythmia (2.0%), headache (2.0%), rash (1.8%), a (1.1%). In addition, the following events were reported infrequently (<1.0%). The order of pr corresponds to the relative frequency of occurrence.

| | |
|---|---|
| Cardiovascular: | Flushing, congestive heart failure, bradycardia, hypotension, syncope, heart |
| Central Nervous System: | Drowsiness, dizziness, lightheadedness, nervousness, depression, wea somnia, confusion, hallucinations |
| Gastrointestinal: | Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis |
| Dermatologic: | Pruritus, petechiae, urticaria |
| Other: | Photosensitivity, nocturia, thirst, paresthesia, polyuria, osteoarticular p |

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

Experience in 959 patients taking oral doses of CARDIZEM resulted in three cases (0.31%) of second block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH have been noted during CARDIZEM therapy. A single incident of markedly elevated liver enzymes asso symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued an normalized within 1 week.

## OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experiences with oral diltiazem have not been reported. Single oral doses of 300 mg of have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, a supportive measures should be employed in addition to gastric lavage. The following measure considered:

| | |
|---|---|
| Bradycardia | Administer atropine (0.60 to 1.0 mg). If there is no response to vagal administer isoproterenol cautiously. |
| High-Degree AV Block | Treat as for bradycardia above. Fixed high-degree AV block should be tr cardiac pacing. |
| Cardiac Failure | Administer inotropic agents (isoproterenol, dopamine or dobutamine) and |
| Hypotension | Vasopressors (eg, dopamine or levarterenol bitartrate). |

Actual treatment and dosage should depend on the severity of the clinical situation and the judg experience of the treating physician.

The oral $LD_{50}$'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respec intravenous $LD_{50}$'s in these species were 60 and 38 mg/kg, respectively. The oral $LD_{50}$ in dogs is consic in excess of 50 mg/kg while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not k blood levels in excess of 800 ng/ml have not been associated with toxicity.

## DOSAGE AND ADMINISTRATION

**Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at R Coronary Artery Spasm.** Dosage must be adjusted to each patient's needs. Starting with 30 mg four ti before meals and at bedtime, dosage should be increased gradually to 240 mg (given in divided doses th times daily) at one- to two-day intervals until optimum response is obtained. The effectiveness and dosages exceeding 240 mg per day are currently being investigated. There are no available data concerni requirements in patients with impaired renal or hepatic function. If the drug must be used in such patient should be carried out with particular caution.

**Concomitant Use With Other Antianginal Agents.**

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM the
2. **Prophylactic Nitrate Therapy** — CARDIZEM may be safely co-administered with short- and l nitrates, but there have been no controlled studies to evaluate the antianginal effectivene combination.
3. **Beta-blockers** (See WARNINGS and PRECAUTIONS).

## HOW SUPPLIED

CARDIZEM 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47). Each green tablet is eng MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in 100 (NDC 0088-1772-47). Each yellow tablet is engraved with MARION on one side and 1772 on the

# Relation of Electrocardiographic Abnormalities and Patterns of Left Ventricular Hypertrophy Identified by 2-Dimensional Echocardiography in Patients With Hypertrophic Cardiomyopathy

BARRY J. MARON, MD, JAMES K. WOLFSON, ELISABETTA CIRÓ, MD, and PAOLO SPIRITO, MD

**Distribution of left ventricular (LV) hypertrophy was assessed by wide-angle, 2-dimensional (2-D) echocardiography in 153 patients with hypertrophic cardiomyopathy and compared with the scalar electrocardiogram in the same patients. The most common electrocardiographic alterations were S-T segment changes and T-wave inversion (61%), LV hypertrophy (47%), abnormal Q waves (25%), and left atrial enlargement (24%). LV hypertrophy on the electrocardiogram was significantly more common in patients with the most extensive distribution of LV hypertrophy on 2-D echocardiogram involving substantial portions of both the ventricular septum and LV free wall (type III; 51 of 69, 74%) than in those with more limited distribution of LV hypertrophy (21 of 84, 25%; $p < 0.001$). Most patients with hypertrophic cardiomyopathy and *normal* electrocardiograms (13 of 23) had localized (type I) hypertrophy, but only 4 had the extensive type III pattern of hypertrophy.**

**Abnormal Q waves were significantly more common in those patients without hypertrophy of the anterior, basal septum (type IV; 15 of 27, 56%) than in those with basal septal hypertrophy (23 of 126, 18%; $p < 0.001$); abnormal Q waves were uncommon in extensive type III distribution of hypertrophy (13 of 69, 19%).**

**Thus, although no single electrocardiographic abnormality is characteristic of hypertrophic cardiomyopathy, 2-D echocardiography clarifies the significance of certain electrocardiographic patterns: (1) LV hypertrophy on the electrocardiogram, although present in only about half of the study group, was a relatively sensitive (74%) marker for extensive (type III) LV hypertrophy; (2) abnormal Q waves cannot be explained by ventricular septal hypertrophy alone; and (3) a normal electrocardiogram was most commonly a manifestation of localized LV hypertrophy.**

A variety of abnormalities may be present in the 12-lead electrocardiogram in patients with hypertrophic cardiomyopathy.[1–5] Electrocardiographic changes in such patients have been reported to show little relation to the morphologic and functional changes identified by M-mode echocardiography.[2–5] Recent studies with wide-angle, 2-D echocardiography in patients with hypertrophic cardiomyopathy[6,7] have demonstrated a variety of patterns of distribution of hypertrophy, not appreciated by M-mode echocardiography alone. Hence, we examined the relation between the extent and distribution of LV hypertrophy assessed by 2-D echocardiography and abnormalities on the 12-lead electrocardiogram in a large group of patients with hypertrophic cardiomyopathy, in an attempt to clarify the significance of electrocardiographic patterns in this disease.

From the Echocardiography Laboratory and Cardiology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Manuscript received May 3, 1982; revised manuscript received July 1, 1982, accepted July 2, 1982.

Address for reprints: Barry J. Maron, MD, Building 10, Room 7B-15, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland 20205.

## Selection of Patients

Between February and November 1979, 186 patients with a diagnosis or a suspected diagnosis of hypertrophic cardiomyopathy (by virtue of personal or family history, physical examination, or M-mode echocardiographic or hemodynamic and angiographic studies) at the National Heart, Lung, and Blood Institute were studied with 2-D echocardiography. Of the 186 patients, 125 were selected for the study group because they were considered to have undergone technically satisfactory

2-D echocardiographic examination; that is, there was acceptable recognition of the endocardial and epicardial borders of the LV free wall, and delineation of the boundaries of the ventricular septum was obtained in at least the short- and long-axis views.[6] In addition, 28 other patients with hypertrophic cardiomyopathy not surgically treated and with a technically satisfactory 2-D echocardiogram were added to the study group: (1) 13 patients in the 2 echocardiographically defined morphologic groups[6,7] with the smallest number of patients (types I and IV as described later) evaluated after November 1979; and (2) 15 patients with no abnormality on any recorded 12-lead electrocardiogram. These 15 patients and 9 others with a normal electrocardiogram (who are included in the consecutive group of 125 patients just described) constitute the total number of 24 patients with hypertrophic cardiomyopathy and a normal electrocardiogram evaluated at the National Heart, Lung, and Blood Institute.

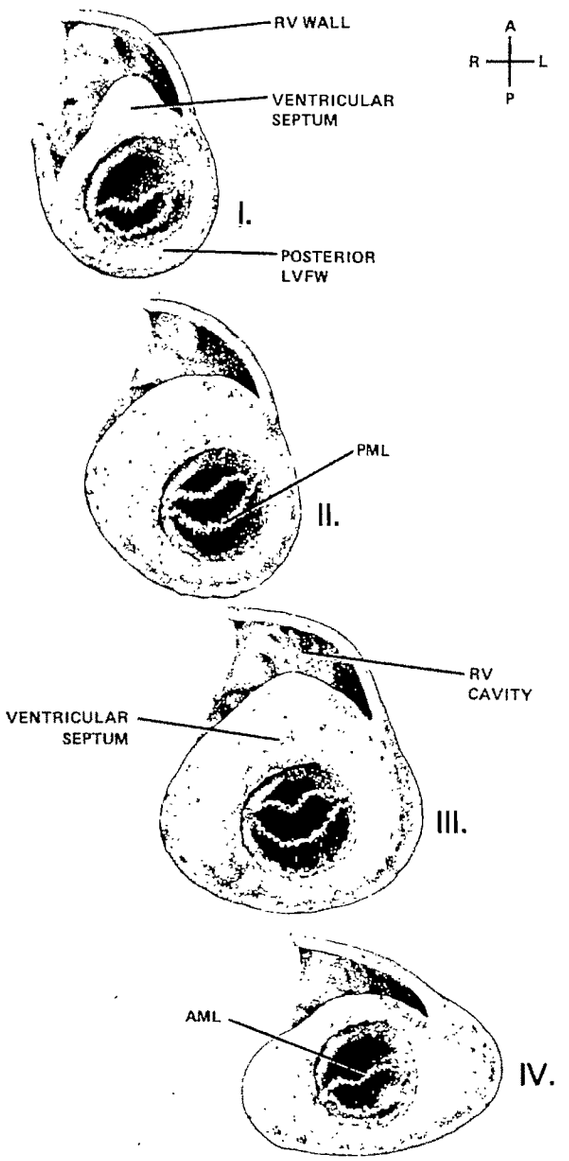

**FIGURE 1.** Artistic representation of the 4 patterns of hypertrophy identified by wide-angle 2-D echocardiography in 153 patients with hypertrophic cardiomyopathy. Shown only in cross-sectional (short-axis) planes at the level of the mitral valve. A = anterior; AML = anterior mitral leaflet; L = (patient's) left; LVFW = left ventricular free wall; P = posterior; PML = posterior mitral leaflet; R = (patient's) right; RV = right ventricular.

Hence, 153 patients with hypertrophic cardiomyopathy comprised the overall study group. In these patients, the diagnosis of hypertrophic cardiomyopathy was established with either M-mode or 2-D echocardiography by the demonstration of a nondilated, hypertrophied left ventricle in the absence of another cardiac or systemic disease which itself could produce left ventricular hypertrophy.[8] Specifically, no study patient was known to have coronary heart disease, systemic hypertension, or valvular heart disease.

## Characterization of Patients

The 153 study patients ranged in age from 5 to 69 years (mean 36). Ninety patients (59%) were male and 63 (41%) were female. Of the 153 patients, 48 (31%) had no functional limitation (New York Heart Association class I[9]), 41 (27%) had mild symptoms (functional class II), and 64 (42%) had moderate to severe functional limitation (classes III and IV).

The magnitude of LV outflow tract obstruction under basal conditions was assessed at cardiac catheterization (97 patients) or was estimated from the M-mode echocardiogram based on the magnitude and duration of systolic anterior motion of the anterior mitral leaflet (56 patients).[10] Outflow obstruction (gradient ≥30 mm Hg) was present at rest in 51 patients and was minimal (<30 mm Hg) or absent in the other 102 patients. Ninety-five of the 153 patients were taking cardioactive medication at the time of electrocardiographic study, including 66 receiving propranolol, 14 verapamil, 9 digitalis, and 6 quinidine.

## Methods

**M-mode echocardiography:** M-mode echocardiography was performed with use of a 2.25 MHz, 1.25 cm diameter unfocused Aerotech transducer and a Hoffrel 201 ultrasonic receiver interfaced with a Honeywell 1856 strip chart recorder. The methods utilized for imaging the ventricular septum and posterior LV free wall have previously been described.[11] Maximal thickness of the ventricular septum was measured just before atrial systole with the ultrasonic beam directed through or slightly below the caudal margins of the mitral leaflets. Thickness of the posterior LV free wall was measured during the same phase of the cardiac cycle, with the ultrasonic beam passing through the mitral leaflet tips.

**Two-dimensional echocardiography:** A Varian (V-3400) real-time, phased-array, 80° ultrasonic sector scanner with hand-held 2.25 MHz transducer was used to perform 2-D echocardiographic studies. The 2-D echocardiographic examination included the imaging of a number of cross-sectional planes through the heart. Serial short-axis views of the left ventricle were obtained by initially orienting the sector plane perpendicular to the long axis of the left ventricle from a standard transducer placement on the chest. The "short-axis sweep" was performed by maintaining the transducer in a fixed location on the chest wall and slowly angling the image plane from aorta (cephalad) to apex (caudad).[12] However, in the short-axis view, ultrasonic beam angulation from a single fixed transducer location prohibits imaging multiple cross-

sectional planes that are truly perpendicular to the cephalad-caudad axis. The apical portions of the anterior regions of the LV wall (that is, the anterior ventricular septum and anterior free wall) that are not well visualized in the short-axis plane are, however, often visualized in the long-axis and apical views.

The long-axis view was obtained by orienting the sector plane 90° to the short-axis plane and parallel to the longitudinal axis of the left ventricle, taking care to avoid improper angulation of the scan plane tangentially through the ventricle. The apical 4-chamber view was obtained with the transducer placed at the cardiac apex and the tomographic plane directed perpendicular to the ventricular and atrial septa and through the plane of the mitral and tricuspid valve orifices to permit simultaneous display of both atria and ventricles, atrioventricular valves, and cardiac septa.[13]

The location of regions of hypertrophy was identified in 2 cross-sectional planes according to previously described criteria.[6,7] In the anteroposterior plane, hypertrophy was designated as involving either the ventricular septum or the LV free wall. The ventricular septum was divided into 2 approximately equal-sized segments: anterior and posterior. The LV free wall was divided into 3 segments: the anterior, lateral, and posterior. In the cephalad-caudad plane the left ventricle was divided into 2 segments: the basal portion that extends from cardiac base to the inferior margins of the mitral leaflets, and the apical portion which included that portion of the left ventricle imaged caudal to the mitral leaflets.

**Echocardiographic classification of morphologic types:** Four basic patterns of distribution of LV hypertrophy were identified by 2-D echocardiography in the study patients. This classification has previously been described in detail,[6] but for the purposes of this study is also described briefly here.

In *type I* hypertrophy was confined to the anterior segment of the ventricular septum, usually the basal region alone but often both the basal and apical portions; the LV free wall and posterior portion of ventricular septum appeared essentially normal. In *type II*, hypertrophy involved both the anterior and posterior segments of the ventricular septum; the left ventricular free wall appeared essentially normal. In *type III*, hypertrophy involved substantial portions of both the ventricular septum and anterolateral LV free wall; the predominant region of hypertrophy was usually in the anterior or posterior segment of the ventricular septum, and often the only region of the LV wall free of hypertrophy was the posterior free wall. In *type IV*, hypertrophy involved regions of the LV wall, other than the anterior basal ventricular septum, that is, the posterior segment of the septum, anterolateral free wall, or the ventricular septum in its apical half. In each patient with type IV, M-mode echocardiography failed to show evidence of hypertrophy because LV wall thickening was situated in regions of the left ventricle that were inaccessible to the path of the conventional M-mode ultrasonic beam. However, 2-D echocardiography did permit identification of these regions of LV hypertrophy not visualized by M-mode echocardiography.[7] Patients with type IV hypertrophy were usually suspected clinically of having hypertrophic cardiomyopathy because of a distinctly abnormal scalar electrocardiogram (which most often showed deep Q waves, T-wave inversion, or right ventricular hypertrophy) and a family history of hypertrophic cardiomyopathy.

**Electrocardiographic procedure and criteria:** Standard 12-lead electrocardiography was performed with patients in the supine position during quiet respiration. Either a Sanborn heat-sensitive paper or a Marquette ink-writer electrocardiographic machine was used. The electrocardiogram was recorded on the same day the 2-D echocardiogram was performed in 122 (80%) of the patients, within 1 week of the echocardiogram in 15 (10%) other patients, within 5 months in 13 patients (8%), and within 12 or 18 months in the remaining 3 patients (2%).

The electrocardiograms were interpreted using criteria similar to those previously described in detail,[4] but with certain modifications. In particular, LV hypertrophy was diagnosed using the point-score system of Romhilt and Estes[14] for patients over 16 years of age; 5 or more points were considered indicative of LV hypertrophy. For the 22 study patients under 16 years of age, the criteria of Davignon et al,[15] Liebman and Plonsey,[16] and Cassels and Ziegler[17] were used.

Q or QS waves were considered abnormal if they were ≥0.04 second in duration or ≥3 mm deep, and were present in ≥2 leads. Q or QS waves present only in leads $V_1$ and $V_2$ were not considered abnormal. S-T segment and T-wave alterations that were judged secondary effects of digitalis administration were not tabulated as true abnormalities. Patterns suggestive of right ventricular hypertrophy were rightward mean QRS axis in the frontal plane (between +110° and +180°) or an R/S ratio ≥1 in lead $V_1$.

**Statistical analyses:** When appropriate, Student's *t* test or the chi-square test was used to assess statistical significance.

Abn = abnormal; AF = atrial fibrillation; ECG = electrocardiogram; LAE = left atrial enlargement; RAE = right atrial enlargement; LVH = left ventricular hypertrophy; RVH = right ventricular hypertrophy; ST-T = S-T segment and T wave.

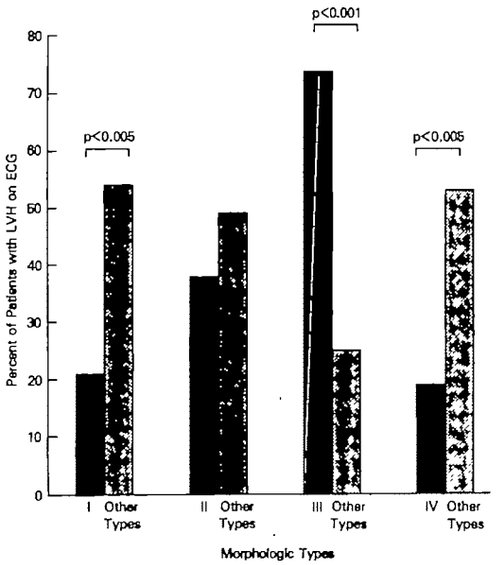

**FIGURE 2.** Prevalence of left ventricular hypertrophy (LVH) on electrocardiography (ECG) in the 4 morphologic types identified by 2-D echocardiography in 153 patients with hypertrophic cardiomyopathy.

## Results

**Electrocardiography:** Twelve-lead electrocardiograms were abnormal in 130 patients (85%). A wide variety of electrocardiographic abnormalities were present, although no particular pattern was characteristic of the study group (Table I). The most common abnormalities were S-T segment changes or T-wave inversion (93 patients, 61%), or both, LV hypertrophy (72 patients, 47%, including 36 patients with "strain" pattern), Q waves (38 patients, 25%), and left atrial enlargement (36 patients, 24%). Patients with obstruction to LV outflow under basal conditions more commonly demonstrated LV hypertrophy on electrocardiography (38 of 51, 75%) than did patients without obstruction to outflow (34 of 102, 33%; $p < 0.001$).

**M-mode echocardiography:** Ventricular septal thicknesses ranged from 6 to 41 mm (mean 21); posterior LV free wall thickness ranged from 6 to 17 mm (mean 12). In 123 patients (80%) the septal to free wall thickness ratio was $\geq 1.3$, meeting our criterion for asymmetric septal hypertrophy.[10] Concentric (symmetric) LV wall thickening (septal-free wall thickness ratio $< 1.3$) was present in 3 (2%) of the patients; the remaining 27 patients (18%) had both normal septal-free wall ratio and ventricular wall thicknesses.[7] Ventricular septal thickness, posterior free wall thickness, and septal-free wall thickness ratio were significantly greater in patients with LV hypertrophy on electrocardiography ($24 \pm 0.8$ mm, $13 \pm 0.3$ mm, and $1.9 \pm 0.1$, respectively) than in patients without LV hypertrophy on electrocardiography ($18 \pm 0.8$ mm, $12 \pm 0.3$ mm, $1.5 \pm 0.5$; $p < 0.005$).

**Two-dimensional echocardiography:** Four patterns of distribution of LV hypertrophy were identified.[6] The largest subgroup of patients (69 of 153, 45%) showed extensive hypertrophy involving substantial portions of both ventricular septum and anterolateral LV free wall (that is, type III) (Fig. 1). Thirty-three other patients had hypertrophy localized to only the

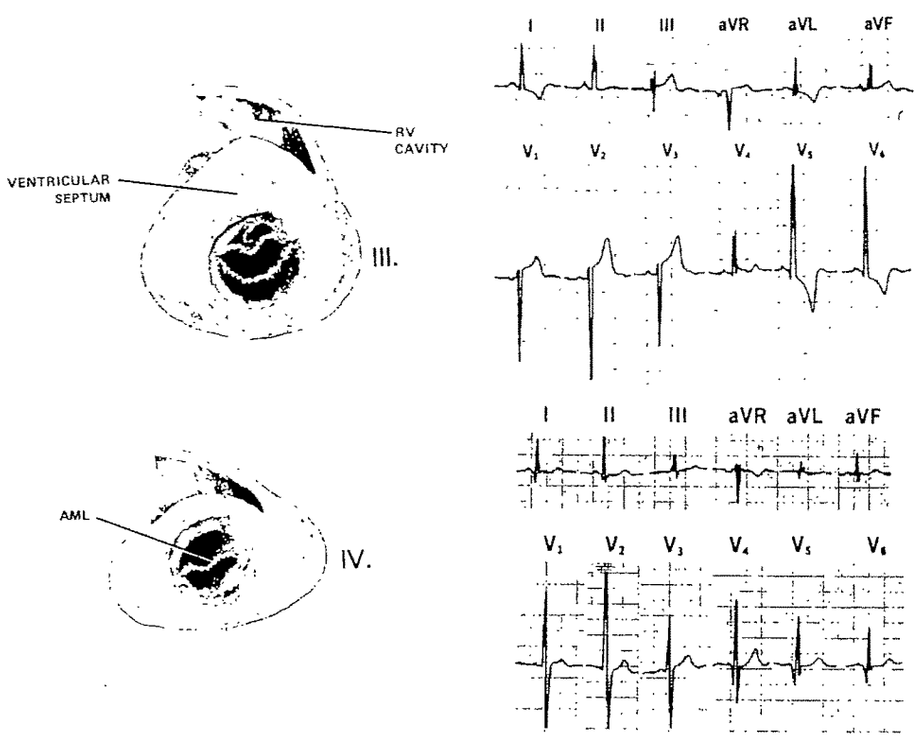

**FIGURE 3.** Typical electrocardiographic patterns that occur in patients with morphologic types III and IV. **Top,** electrocardiogram in a patient with morphologic type III showing LV hypertrophy with a "strain" pattern as well as T-wave abnormalities in standard leads. **Bottom,** electrocardiogram in a patient with morphologic type IV showing deep Q waves in the left precordial leads and a pattern consistent with right ventricular hypertrophy in the right precordial leads. AML = anterior mitral leaflet; RV = right ventricular.

anterior (and usually basal) portion of ventricular septum (type I); in these patients the LV free wall and other portions of the ventricular septum did not appear thickened. Twenty-four patients had substantial hypertrophy involving most or all of the ventricular septum (type II); the LV free wall did not appear thickened. The remaining 27 patients had unusually located regions of hypertrophy involving portions of the left ventricle other than the anterobasal ventricular septum (usually the posterior segment of septum, anterolateral free wall, or septum in the apical region (type IV). Conventional M-mode echocardiography failed to show evidence of hypertrophy in the latter patients since the M-mode beam could not traverse those regions of the LV wall that were thickened, and hence the diagnosis of hypertrophic cardiomyopathy could be established only by 2-D echocardiography.[7]

**Relation of electrocardiographic and 2-D echocardiographic abnormalities:** The electrocardiographic diagnosis of LV hypertrophy was present in patients with each of the 4 patterns of hypertrophy identified by 2-D echocardiography. However, left ventricular hypertrophy on electrocardiography was significantly more common in patients with morphologic type III (51 of 69, 74%) than in each of the other 3 morphologic types individually or in combination (21 of 84, 25%; $p < 0.001$; Fig. 2 and 3). In addition, left atrial enlargement (27 of 69, 39%) was significantly more common in patients with type III than in all other morphologic types (9 of 84, 11%; $p < 0.001$).

Abnormal Q waves were significantly more common in patients with morphologic type IV (15 of 27, 56%) than in patients with the other 3 types combined (23 of 126, 18%; $p < 0.001$; Fig. 3 and 4). Of the 15 patients with type IV and Q waves in the electrocardiogram, LV hypertrophy was present either in the anterolateral free wall (8 patients), the posterior segment of the septum (1 patient), both the posterior septum and anterolateral free wall (5 patients), or the ventricular septum in its apical portion (1 patient). Abnormal Q waves were uncommon in patients with extensive type III distribution of hypertrophy (13 of 69, 19%).

The electrocardiographic pattern of right ventricular hypertrophy was uncommon (6 of 153 patients, 4%), but occurred almost exclusively in the patients with type IV distribution of hypertrophy (5 of 27, 19%; $p < 0.005$) (Fig. 3). Right atrial enlargement, atrial fibrillation, and conduction abnormalities in the electrocardiogram did not show a statistically significant predilection for any of the morphologic types identified by 2-D echocardiography.

**Patients with normal electrocardiograms:** The subgroup of 23 patients with hypertrophic cardiomyopathy and normal electrocardiogram included at least 1 patient with each pattern of LV hypertrophy. Type I, which was the most common morphologic pattern, occurred in 13 patients; 3 patients had type II, 4 had type III, and 3 had type IV (Fig. 5). Hence, the prevalence of a normal electrocardiogram in patients with type I (13 of 33, 39%) was significantly greater than in the other 3 morphologic types combined (10 of 120, 8%; $p < 0.001$).

Patients with a normal electrocardiogram ranged in age from 13 to 67 years (mean 45); 7 patients were asymptomatic, but 16 had cardiac symptoms (including 7 who were in functional class III or IV). Seventeen patients had no evidence of subaortic obstruction under basal conditions, although 6 had outflow gradients >50 mm Hg measured at cardiac catheterization under basal conditions or with provocative maneuvers.

## Discussion

The results of this study confirm that patients with hypertrophic cardiomyopathy exhibit a wide variety of electrocardiographic patterns[1-5] and that no single electrocardiographic abnormality is characteristic of patients with this disease. However, by utilizing 2-D echocardiography to define the distribution of LV hypertrophy in patients with hypertrophic cardiomyopathy, it became apparent that certain electrocardiographic patterns reflected particular patterns of hy-

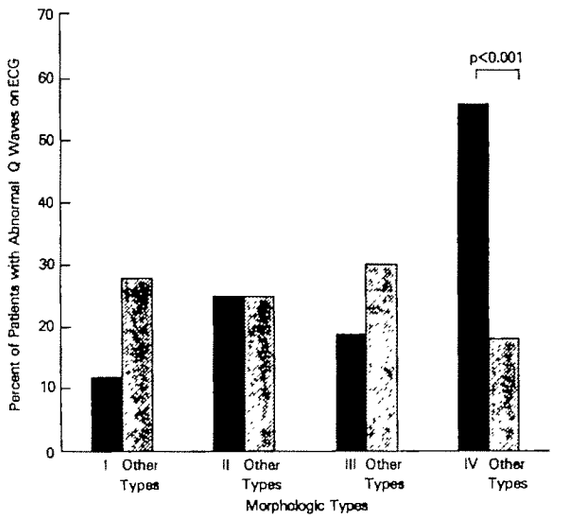

**FIGURE 4.** Prevalence of abnormal Q waves on electrocardiography (ECG) in the 4 morphologic types identified by 2-D echocardiography.

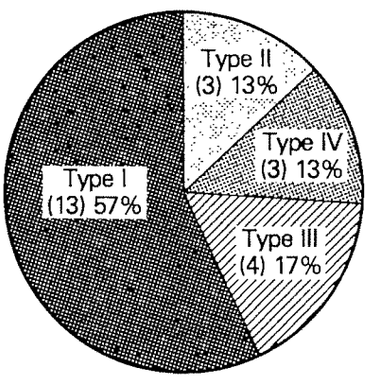

**FIGURE 5.** Frequency of 4 morphologic types identified by 2-D echocardiography in 23 patients with hypertrophic cardiomyopathy and *normal* scalar electrocardiograms.

pertrophy on the 2-D echocardiogram. For example, patients with the widespread hypertrophy involving substantial portions of both the ventricular septum and the LV free wall (type III) most commonly manifest LV hypertrophy on electrocardiography (that is, 74%), as well as left atrial enlargement (39%). Conversely, those patients with hypertrophy limited to only the anterior ventricular septum (type I) have electrocardiograms that uncommonly exhibit LV hypertrophy (that is, 21%) and frequently show no abnormalities. Patients with LV hypertrophy on the electrocardiogram also have significantly greater ventricular septal and posterior free wall thicknesses and septal-free wall ratio than do patients without electrocardiographic evidence of LV hypertrophy (Fig. 6). In addition, obstruction to LV outflow under basal conditions is more commonly associated with LV hypertrophy on the electrocardiogram (Fig. 6).

A substantial number of patients with hypertrophic cardiomyopathy have electrocardiograms that either fail to show LV hypertrophy or are entirely normal.[2,4,5] Several factors may be responsible for this finding. First, the relatively poor intrinsic sensitivity of the electrocardiogram for detecting LV hypertrophy is well documented.[14,18–22] Second, the fact that hypertrophy may be localized to particular portions of the LV wall could have been responsible, in part, for "false-negative" electrocardiograms in some patients. For example, we found that the majority of our patients with a normal electrocardiogram had localized type I hypertrophy. Such patients with morphologic type I uncommonly meet electrocardiographic criteria for LV hypertrophy because the hypertrophy is localized in distribution and overall LV mass is only slightly increased over normal. Such a mild degree of LV hypertrophy is less likely to be reflected by increased voltages in the electrocardiogram.

Other investigators have concluded that Q waves, when present in patients with hypertrophic cardiomyopathy, originate from increased initial depolarization of the markedly hypertrophied ventricular septum.[23–27] However, our data indicate that Q waves were present in only about 20% of those patients showing the most substantial involvement of the ventricular septum (that is, morphologic types II and III). Furthermore, abnormal Q waves were most common in those patients with hypertrophy involving regions of the left ventricle other than the anterior basal septum (type IV). Hence, while our study can not define the precise origin of Q waves in hypertrophic cardiomyopathy, our data do suggest that these Q waves in the electrocardiogram are not simply related to depolarization of the greatly thickened ventricular septum.

# Comparative Effects of Nifedipine, Verapamil, and Diltiazem On Experimental Pulmonary Hypertension

THOMAS E. YOUNG, MD, LUCY J. LUNDQUIST, BS, ELLIOT CHESLER, MD, and E. KENNETH WEIR, MD

**The role of calcium-channel blocking agents in the treatment of pulmonary hypertension is not well defined. Consequently, the effects of diltiazem, nifedipine, and verapamil were compared in 3 groups of anesthetized dogs (n = 6 for each group). In each group, normoxic hemodynamic variables were recorded before and after increasing doses of diltiazem, nifedipine, and verapamil ($5 \times 10^{-8}$ *M*/kg, low; $10^{-7}$ *M*/kg, medium; and $10^{-6}$ *M*/kg, high dose; given intravenously over 2 minutes). In addition, the effect of these doses on the pulmonary pressor responses to hypoxia (fractional inspired oxygen concentration [$FIO_2$] 12%) and prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) (5 μg/kg/min, intravenously for 4 minutes) was measured.**

**During normoxia, high-dose nifedipine and verapamil decreased mean aortic pressure and systemic vascular resistance while increasing cardiac output in all dogs in both groups ($p < 0.01$). Pulmonary vascular resistance, however, remained unchanged. High-dose diltiazem did not significantly alter cardiac output or pulmonary vascular resistance. During acute hypoxic pulmonary hypertension, verapamil decreased cardiac output by 30% ($p < 0.01$) without appreciably altering pulmonary arterial pressure; thus pulmonary vascular resistance increased slightly (4.9 ± 0.6 to 6.4 ± 1.0 mm Hg/liter/min, difference not significant [NS]). Nifedipine decreased hypoxic pulmonary vascular resistance to normoxic values ($p < 0.01$). Cardiac output increased 71% while pulmonary arterial pressure remained unchanged. Diltiazem administration produced no change in hypoxic pulmonary hemodynamic variables.**

**The responses to diltiazem, nifedipine, and verapamil during acute pulmonary vasoconstriction induced by $PGF_{2\alpha}$ were similar to those induced by hypoxia. After verapamil, pulmonary vascular resistance tended to increase (7.3 ± 1.3 to 8.1 ± 1.4 mm Hg/liter/min, NS). Nifedipine, however, completely blocked pulmonary vasoconstriction by decreasing pulmonary vascular resistance to pre-$PGF_{2\alpha}$ levels ($p < 0.01$). This was accompanied by a 157% increase in cardiac output and only a small increase in pulmonary arterial pressure (7 mm Hg). Again, diltiazem produced no change in pulmonary hemodynamic variables. In these acute studies, nifedipine appeared to be a more effective pulmonary vasodilator than verapamil or diltiazem.**

Vasodilator agents used in the treatment of pulmonary hypertension may be classified into 4 groups: beta-adrenergic agonists,[1,2] alpha-adrenergic blockers,[3] calcium-channel blockers,[4,5] and finally, those that act directly on vascular smooth muscle such as diazoxide[6,7] and hydralazine.[8] No single drug has been found effective in all patients with pulmonary hypertension, and most drugs have potentially serious adverse effects. As a result, new vasodilators are tried empirically as they become available. Hemodynamically, the most adverse potential effect of a vasodilator agent is systemic vasodilatation and hypotension in the absence of pulmonary vasodilatation.[9] The ideal drug for the treatment of pulmonary hypertension should produce pulmonary vasodilatation with little or no change in systemic pressure.

Different calcium-channel blocking agents have been reported effective[4,5,10] or relatively ineffective[11] in the treatment of pulmonary hypertension, but clinical experience is limited. The calcium antagonists that have been most extensively studied—diltiazem, nifedipine, and verapamil—vary considerably in their pharmaco-

logic characteristics.[12] Consequently, we compared their acute effects on the pulmonary and systemic vascular circuits in 2 experimental models of pulmonary hypertension, produced by hypoxia or $PGF_{2\alpha}$ in the anesthetized dog.

## Methods

Eighteen mongrel dogs of both sexes (mean weight 22 ± 1 kg) were anesthetized with pentobarbital sodium (30 mg/kg intravenously), paralyzed with succinyl choline (2 mg/kg intravenously), intubated with an endotracheal tube, and ventilated on room air with a Harvard respirator (Harvard Apparatus, Millis, Massachusetts). Additional doses of pentobarbital sodium (15 mg/kg intravenously) were given during the experiment to maintain anesthesia. The respirator was adjusted initially to maintain a systemic arterial pH of approximately 7.39. Ventilation was therefore maintained constant throughout the experiment. Care was taken to "sigh" the dogs at regular intervals and to maintain an esophageal temperature of 38.0 to 39.5°C. Polyethylene catheters were placed into the superior and inferior vena cavae and in the descending aorta. A Swan-Ganz balloon tipped catheter was advanced into a branch of the pulmonary artery. Pulmonary artery, pulmonary artery wedge, and aortic pressures were measured using Statham P23 transducers (Statham Instruments, Oxnard, California) and a Hewlett-Packard 8-channel recorder (Hewlett-Packard, Waltham, Massachusetts). Cardiac output was determined by injecting 1.25 mg indocyanine-green dye into the inferior vena cava and withdrawing blood from the aorta at 20 ml/min through a Waters cuvette densitometer (Waters Instruments, Rochester, Minnesota). Pulmonary vascular resistance was calculated as mean pulmonary arterial pressure minus the wedge pressure (mm Hg) divided by the cardiac output (liters/min). Systemic arterial oxygen and carbon dioxide tensions and pH were measured with a Corning model 168 pH blood gas analyzer (Corning Glass Works, Medfield, Massachusetts).

In all dogs, pulmonary and systemic hemodynamic variables (pressures, cardiac output, and systemic blood gases) were recorded in the control state (normoxia) and after 8 and 15 minutes of hypoxia (12% $FIO_2$). For presentation and calculation of statistics, the hemodynamic values recorded during hypoxia at 8 and 15 minutes were averaged to give 1 hypoxic value. After hypoxia, the pressures were allowed to return to baseline level, where recontrol normoxic hemodynamic variables were recorded. $PGF_{2\alpha}$ (5 μg/kg/min) was then infused into the superior vena cava and hemodynamic values were recorded after 4 minutes. Once again, the pressures were allowed to return to baseline level and recontrol hemodynamic values recorded.

At this point, 6 dogs (Group 1) were treated with diltiazem, 6 dogs (Group 2) with nifedipine, and 6 dogs (Group 3) with verapamil in equimolar doses ($5 \times 10^{-8}$ *M*/kg intravenous bolus, low dose). Solutions of diltiazem and verapamil were made daily by dissolving the drug in saline solution. Nifedipine solution was prepared by dissolving the agent in absolute ethyl alcohol, then combining this with polyethylene glycol as the vehicle. Ten minutes after administration of low-dose drug, hemodynamic data were recorded. All groups were then challenged with hypoxia, followed by administration of $PGF_{2\alpha}$ as before.

In order to examine any hemodynamic effect of the vehicle, hemodynamics were recorded immediately before and 5 minutes after the administration of the vehicle (saline solution in Groups 1 and 3, polyethylene glycol in Group 2) without the drug. At this point, the whole protocol including normoxia, hypoxia, and $PGF_{2\alpha}$ was repeated after the administration of diltiazem, nifedipine, and verapamil in increasing equimolar doses ($10^{-7}$ *M*/kg, medium dose; and $10^{-6}$ *M*/kg, high dose).

**Statistical analysis:** The data are given as means ± standard error of the mean. Statistical analyses were performed using one-way analysis of variance (ANOVA) for repeated measurements within individual groups. The least significant difference[13] was employed to assess the significance of differences between groups. A p value <0.05 was considered statistically significant.

## Results

**Normoxia:** Figure 1 illustrates the systemic and pulmonary vascular effects of an equimolar dose ($10^{-6}$ *M*/kg, high dose) of diltiazem, nifedipine, or verapamil during normoxic conditions. Diltiazem caused a small decrease in aortic pressure (133 ± 5 to 125 ± 5 mm Hg) but no significant change in pulmonary hemodynamics. In contrast, nifedipine and verapamil produced marked changes in hemodynamic values. Both nifedipine and verapamil produced a decrease in aortic pressure and a concomitant increase in cardiac output ($p < 0.01$). Pulmonary arterial pressure increased ($p < 0.05$), and the calculated pulmonary vascular resistance showed a small, statistically insignificant decrease. Both nifedipine and verapamil resulted in similar pulmonary and systemic hemodynamic changes; however, the changes associated with nifedipine were more pronounced.

Figure 2 shows the relation between cardiac output and pulmonary arterial pressure in Groups 1, 2, and 3 with low-, medium-, and high-dose drug during normoxia. With the use of vectors to represent the cumulative effect, it can be seen that in equimolar doses the

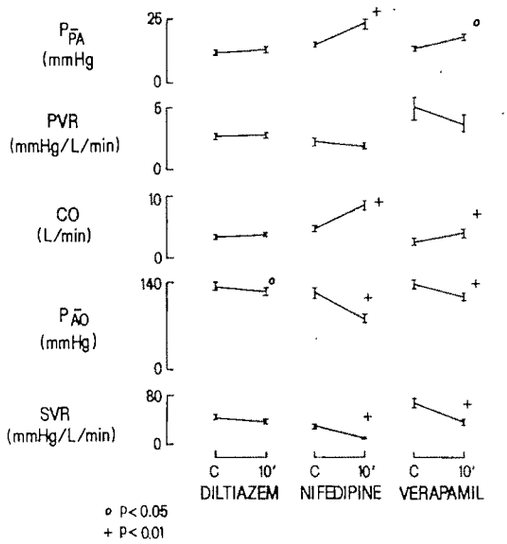

**FIGURE 1.** Comparative effects of equimolar high dose ($10^{-6}$ *M*/kg) drug during normoxia. Hemodynamic effects were measured before (C) and 10 minutes (10') after infusion of the drug. The statistical comparison is between the data obtained at these 2 times. **Bars** represent standard error of the mean. CO = cardiac output; $P_{\bar{AO}}$ = mean aortic pressure; $P_{\bar{PA}}$ = mean pulmonary arterial pressure; PVR = pulmonary vascular resistance; SVR = systemic vascular resistance.

CO = cardiac output; $P_{\overline{AO}}$ = mean aortic pressure; $P_{\overline{PA}}$ = mean pulmonary arterial pressure; PVR = pulmonary vascular resistance; SVR = systemic vascular resistance.

3 drugs behaved quite differently. The length of the added vectors as well as the angle of the vectors differs for each drug. Nifedipine caused an increase in pulmonary arterial pressure and a very marked increase in cardiac output with increasing doses, in a linear relation ($r = 0.98$). On the other hand, with increasing doses, verapamil decreased cardiac output as well as pulmonary arterial pressure. Diltiazem produced very little change in either pulmonary arterial pressure or cardiac output with increasing doses, as evidenced by the small magnitude of its combined vector.

**Hypoxia:** The hypoxic challenge induced a marked increase in pulmonary arterial pressure ($p < 0.01$) and pulmonary vascular resistance ($p < 0.01$) in each group (Table I).

Figure 3 illustrates the systemic and pulmonary hemodynamic effects of equimolar doses of diltiazem, nifedipine, and verapamil during hypoxia. Hemody-

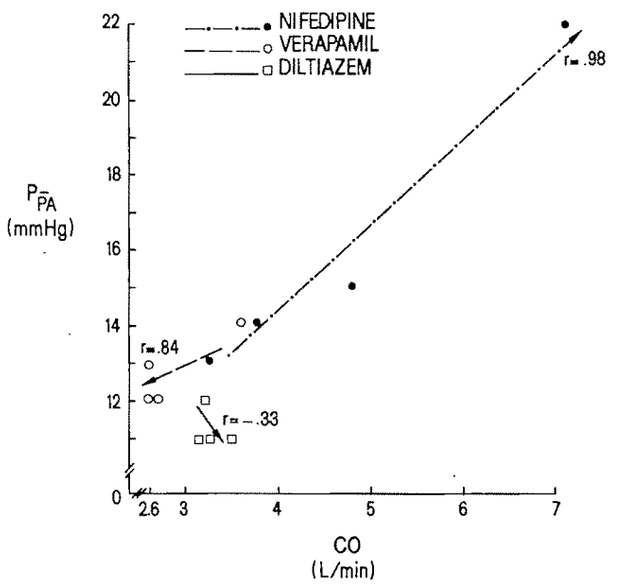

**FIGURE 2.** Comparative effects of increasing dose of diltiazem, nifedipine, and verapamil on the relation of cardiac output to pulmonary arterial pressure during normoxia. In each drug group there are 4 points: the control, followed by values obtained 15 minutes after low-, medium-, and high-dose drug. The magnitude and the angle between each 2 successive points for each group were measured and converted into a vector, and the resulting 3 vectors were added to give a single combined vector for that group, shown by the **lines with arrows.** CO = cardiac output; $P_{\overline{PA}}$ = mean pulmonary arterial pressure.

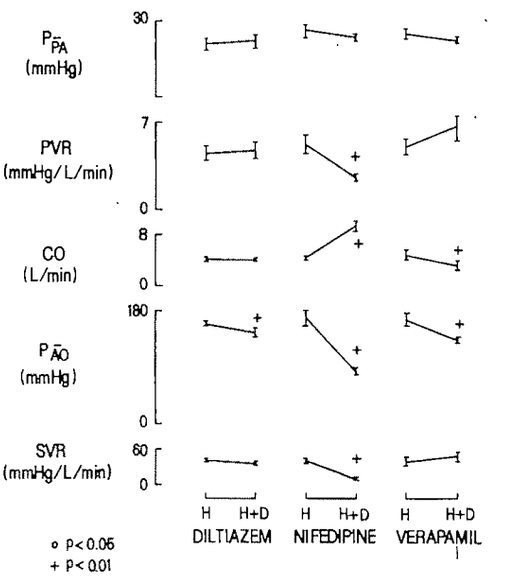

**FIGURE 3.** Comparative effects of equimolar high-dose ($10^{-6}$ *M*/kg) drug during hypoxic ($FIO_2$ 12%) pulmonary vasoconstriction. Hemodynamic affects were measured during hypoxia (H) and during hypoxia with high-dose drug (H + D). The statistical comparison is between the data obtained at these 2 times. **Bars** represent standard error of the mean. Abbreviations as in Figure 1.

**TABLE II Hemodynamic Effects of $PGF_{2\alpha}$ and $PGF_{2\alpha}$ Plus High-Dose Drug**

| | $P_{\overline{AO}}$ (mm Hg) | $P_{\overline{PA}}$ (mm Hg) | CO (liters/min) | SVR (mm Hg/liter/min) | PVR (mm Hg/liter/min) |

Abbreviations as in Table I.

namic values were recorded during the initial hypoxic challenge before treatment (see Methods) and the data were compared with recordings made during hypoxia after administration of high-dose drug. Diltiazem had no significant effect on pulmonary hemodynamic function. However, systemic arterial pressure did decrease (160 ± 3 to 146 ± 6 mm Hg) ($p < 0.01$). Nifedipine, in contrast to diltiazem, markedly blunted the hypoxic vasoconstrictor response. During the hypoxic challenge nifedipine increased cardiac output by 71%; at the same time pulmonary arterial pressure was, if anything, slightly decreased, thus suggesting pulmonary vasodilatation, as indicated by the 52% decrease in pulmonary vascular resistance. Systemic hemodynamic effects were also altered by nifedipine. Aortic pressure and systemic vascular resistance both decreased considerably ($p < 0.01$ for both). The administration of verapamil did not alter pulmonary arterial pressure. However, cardiac output showed a small decrease and consequently pulmonary vascular resistance tended to increase.

**$PGF_{2\alpha}$:** $PGF_{2\alpha}$ was used as a second independent agent to provoke pulmonary hypertension. In each group of dogs, the $PGF_{2\alpha}$ challenge induced a marked increase in pulmonary arterial pressure ($p < 0.01$) and pulmonary vascular resistance ($p < 0.01$), without a change in cardiac output (Table II). The hemodynamic effects of diltiazem, nifedipine, and verapamil on $PGF_{2\alpha}$-induced pulmonary vasoconstriction are compared in Figure 4.

Diltiazem had no effect on hemodynamic function and did not blunt the $PGF_{2\alpha}$ vasoconstriction. With high-dose nifedipine there was a remarkable increase in cardiac output of 156%. This was associated with a relatively small increase in pulmonary arterial pressure of 32% or 7 mm Hg. This resulted in a calculated decrease in pulmonary vascular resistance of 46%, or nearly half. Medium-dose nifedipine increased cardiac output 55%. Pulmonary arterial pressure was not significantly altered at this dose, but pulmonary vascular resistance again decreased significantly.

The response of the pulmonary hypertension induced by $PGF_{2\alpha}$ to verapamil was nearly identical to that of hypoxia-induced pulmonary hypertension. Verapamil reduced cardiac output by 21%, although this was not statistically significant. There was an associated reduction in pulmonary arterial pressure. Pulmonary vascular resistance tended to increase, but not significantly.

**Effect of vehicle:** Hemodynamic measurements were recorded 5 minutes after the administration of the vehicle (saline solution in Groups 1 and 3 and polyethylene glycol in Group 2) alone without the drug. In no case in any group was any change in hemodynamic function noted.

**Dose response of pulmonary vascular resistance to nifedipine:** The response of pulmonary vascular resistance to increasing doses of nifedipine in both models of acute pulmonary vasoconstriction, hypoxia, and $PGF_{2\alpha}$ is illustrated in Figure 5. As the dose of nifedipine was increased, pulmonary vascular resistance decreased in a linear fashion. At the high dose of nifedipine, pulmonary vascular resistance decreased to the control normoxic values, indicating complete blunting of the pulmonary vasoconstrictor effect of hypoxia and $PGF_{2\alpha}$

## Discussion

The pathophysiology of the various forms of clinical pulmonary hypertension is largely unknown. This is true whether the initial stimulus is hypoxia, high flow, or idiopathic, as in primary pulmonary hypertension. It is logical to consider the therapeutic potential of calcium-channel blocking agents, since they are known to relax vascular smooth muscle and inhibit platelet aggregation.[14] Verapamil has been observed to inhibit the pulmonary pressor response to acute hypoxia in the isolated rat lung,[15] the awake calf,[16] and the anesthetized dog.[17] However, disappointing results have been reported by Landmark et al,[11] who injected verapamil into the pulmonary artery of 12 patients with pulmonary hypertension. Only 3 of their patients had a sig-

nificant decrease in pulmonary vascular resistance, while 10 had a reduction in cardiac output.

Because of the differences in the systemic hemodynamic effects[18] and mechanisms of action[19] observed with several calcium-channel blocking agents, we compared the effectiveness of verapamil, diltiazem, and nifedipine in reducing pulmonary hypertension caused by hypoxia or $PGF_{2\alpha}$. The latter stimulus acts primarily by pharmacomechanical excitation contraction coupling, while the mechanism of hypoxic pulmonary vasoconstriction is unknown. The hemodynamic effect of verapamil during hypoxic pulmonary hypertension in the anesthetized dog mimicked the findings described in patients with pulmonary hypertension. Thus, cardiac output and pulmonary artery pressure decreased slightly while pulmonary vascular resistance was unchanged, compared with the preverapamil hypoxic values. The experiments of Tucker et al[17] in the anesthetized dog,[17] using the same dose of verapamil as our high dose, demonstrated a reduction in hypoxic pulmonary vascular resistance, whereas we found an insignificant increase. This difference seems to reflect the fact that in their series cardiac output increased after verapamil administration, whereas in our study it tended to decrease. It is not clear whether these discrepancies are related to the different hemodynamic responses to hypoxia of highland and lowland dogs,[20] or to the fact that their dogs breathed spontaneously while ours were mechanically ventilated. We observed that the absolute pulmonary arterial pressure attained during an infusion of $PGF_{2\alpha}$ was decreased after verapamil, although pulmonary vascular resistance was unchanged. Tucker et al found that verapamil caused no change in pulmonary perfusion pressure after a bolus of $PGF_{2\alpha}$, but did not measure cardiac output.

While diltiazem decreased aortic pressure during both normoxia and hypoxia, it had no effect on pulmonary vascular hemodynamic function during any of the interventions. Administration of diltiazem (0.2 mg/kg intravenously) in open-chest anesthetized dogs has also been reported to decrease systemic pressures significantly.[21]

The most marked effect of nifedipine under normoxic conditions was a decrease in aortic pressure and a concomitant increase in cardiac output. During normoxia, when the pulmonary vasculature is almost fully dilated, this increased flow was associated with an increase in pulmonary arterial pressure but no change in resistance. When the pulmonary vasculature was preconstricted by hypoxia, administration of nifedipine did not increase pulmonary pressure and the calculated resistance returned to normoxic control values because of the increased cardiac output. In the clinical management of pulmonary hypertension, the ideal response to therapy is both a reduction in pulmonary arterial pressure and an increase in cardiac output to normal levels. However, as in these nifedipine studies, it is more common for vasodilators to increase cardiac output with little or no reduction in pulmonary arterial pressure. Patients with primary pulmonary hypertension whose cardiac outputs are in the normal range have been reported to have a better prognosis than those whose cardiac output is diminished.[22] However, an increase in cardiac output induced by vasodilators, without a reduction in pulmonary arterial pressure, increases right ventricular work and it is not known whether the net effect is beneficial in terms of longevity.

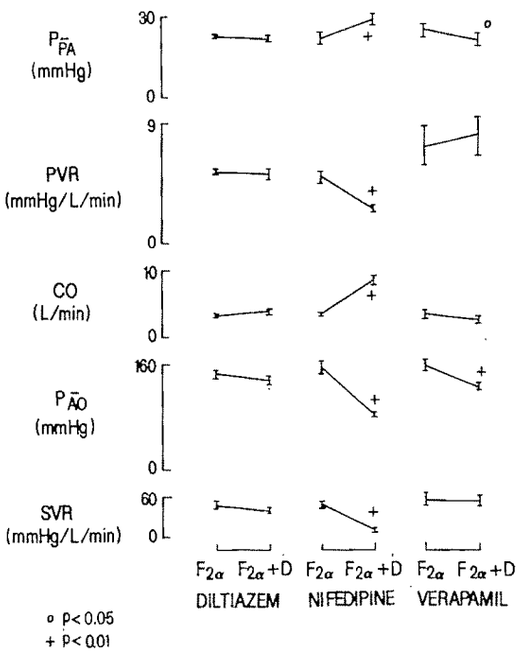

**FIGURE 4.** Comparative effects of equimolar high-dose ($10^{-6}$ *M*/kg) drug during $PGF_{2\alpha}$-induced pulmonary vasoconstriction. Hemodynamic effects were measured during $PGF_{2\alpha}$ vasoconstriction and during $PGF_{2\alpha}$ plus high-dose drug ($F_{2\alpha}$ + D). The statistical comparison is between the data obtained at these 2 times. Abbreviations as in Figure 1.

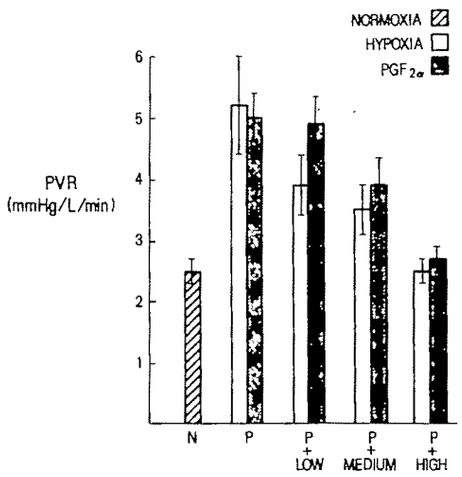

**FIGURE 5.** The effect of increasing doses of nidefipine on pulmonary vasoconstriction stimulated with hypoxia (12% $FIO_2$) or $PGF_{2\alpha}$. N represents pulmonary vascular resistance (PVR) during normoxia for Group 2 dogs before any intervention. P represents the PVR during pressor stimulation. P + LOW, P + MEDIUM, and P + HIGH represent PVR during pressor stimulation plus low-, medium-, or high-dose nifedipine, respectively. **Bars** represent standard error of the mean.

The major problem in the clinical use of vasodilators to treat pulmonary hypertension is that there is no pulmonary hypotensive agent which does not also affect the systemic vasculature. The lack of a selective pulmonary vasodilator gives rise to 2 problems. If the pulmonary vasculature is relatively unresponsive, systemic vasodilatation without an increase in cardiac output may lead to systemic hypotension. Alternately, if cardiac output increases, pulmonary arterial pressure may also increase. In 1 patient with primary pulmonary hypertension reported by Camerini et al,[4] sublingual nifedipine (20 mg) increased cardiac output 90% and decreased pulmonary and systemic vascular resistances by 56 and 49%, respectively.[4] In that patient, pulmonary arterial pressure also decreased. She improved clinically and hemodynamically over the subsequent 3 months on nifedipine and anticoagulants. In this instance the chronic effect of the vasodilator followed the same pattern as the acute response, but frequently this is not the case. Consequently, it is important to be cautious when extrapolating from an acute effect to long-term treatment. Equally, a vasodilator given during acute pulmonary hypertension in the dog may not give the same hemodynamic result when administered to a patient with chronic pulmonary vascular disease. Despite these caveats, the fact that nifedipine returned pulmonary vascular resistance to control levels during hypoxia and $PGF_{2\alpha}$ infusion in the dog, and causes acute pulmonary vasodilatation in patients with respiratory failure,[5] makes it a logical candidate for evaluation in the chronic treatment of clinical pulmonary hypertension.

# Compensatory Cardiac Mechanisms Evoked by Septal Ischemia in Dogs

MÅLFRID MOLAUG, MD, ODD GEIRAN, MD, and FREDRIK KIIL, Dr Med

**To examine the cardiac responses to selective septal ischemia, the septal artery was occluded intermittently in anesthetized open-chest dogs. Myocardial segment length was recorded continuously by an ultrasonic technique in the interventricular septum and the right and left ventricular free walls. At left ventricular end-diastolic pressure of 3.0 ± 0.6 mm Hg, occlusion of the septal artery increased left ventricular end-diastolic segment length by 3.0 ± 0.9% and stroke volume was maintained. After blood volume expansion to a left ventricular end-diastolic pressure of 7.2 ± 1.4 mm Hg, occlusion of the septal artery did not increase end-diastolic dimensions and stroke volume decreased significantly but by <10%. At all levels of blood volume expansion, occlusion of the septal artery did not alter significantly the end-systolic segment length of the free wall of the left ventricle and the dimensions of the free wall of the right ventricle. The distance between the septum and the right ventricular free wall was unchanged in end-diastole and reduced in end-systole after occlusion of the septal artery. These observations indicate paradoxical movement of the ischemic septum. The ischemic septum seems to act as a passive diaphragm pump on the right ventricle without activation of the Frank-Starling mechanism in uninjured areas. In the left ventricle, the Frank-Starling mechanism is fully exploited with unaltered end-systolic dimensions of the uninjured myocardium because of the systolic bulging of the ischemia septum.**

In man, about 80% of the blood supply to the septum is provided by branches from the left anterior descending coronary artery[1] and the rest from short branches of the posterior descending coronary artery. Septal ischemia, therefore, usually occurs together with ischemic lesions of variable extent in the free walls of either ventricle. In contrast, in dogs a separate septal artery originates from the left coronary artery and supplies approximately 75% of the septal myocardium.[2–4] Thus, the anatomy of the coronary circulation in dogs offers a unique possibility to examine the effect of isolated septal ischemia on the pump function of either ventricle.

Septal ischemia might influence the function of both ventricles as blood pumps, but experiments in dogs have shown that ligation of the septal artery has no effect on stroke volume.[5] The compensatory mechanisms which contribute to the maintenance of stroke volume during septal ischemia have not been previously investigated. The objective of the present study was to examine the acute changes in cardiac dynamics induced by intermittent occlusions of the septal artery.

One possibility is that septal ischemia leads to reduced ejection and that the increase in end-diastolic ventricular blood volume increases the activation of the Frank-Starling mechanism in the nonischemic parts of the myocardium. This response has been demonstrated in dogs in the free wall of the left ventricle during acute occlusion of the left anterior descending coronary artery.[6–8] Another possibility is that the ischemic septum bulges into the right ventricular cavity during systole. This paradoxical movement may maintain right ventricular emptying and reduce the end-systolic afterload of the left ventricle.

To examine the compensatory responses to septal ischemia, pairs of ultrasonic elements were inserted into the septum and the free walls of both ventricles of anesthetized open-chest dogs. The distance between the elements—the segment length—was recorded continuously before, during, and after occlusion of the septal artery. These examinations were supplemented by re-

cordings of the distance between the septum and the right ventricular free wall.

The ability of the Frank-Starling mechanism to compensate for myocardial ischemia is reduced during blood volume expansion.[9] Occlusions of the septal artery were therefore repeated at increasing levels of blood volume expansion. This experimental procedure permitted comparisons of right and left ventricular dynamic function with and without septal ischemia at equal end-diastolic segment lengths in the free wall of the left ventricle.

## Methods

**Animal preparation:** Six mongrel dogs of both sexes weighing 17.8 ± 2.2 kg were anesthetized with sodium pentobarbital, 25 mg/kg body weight intravenously initially, followed by 50 mg intravenously as required to maintain anesthesia. The dogs were kept on a positive pressure respirator (Cyclator Mk II, British Oxygen). Throughout the experiments, appropriate measures were taken to keep blood gases and the acid-base balance normal. The heart was exposed by a bilateral thoracotomy and suspended in a pericardial cradle. The septal artery originated either from the brief left main coronary artery at the point of branching or from the left anterior descending coronary artery 1 to 2 mm distal to its origin. After isolation, a thin silicon rubber snare was looped around the septal artery for later occlusion. Care was taken not to obstruct the left anterior descending coronary artery or the circumflex artery.

**Hemodynamic and dimensional measurements:** Right and left ventricular pressures were measured with Statham P23Db and P23Gb transducers connected to short polyethylene catheters introduced into the right ventricle through the outflow tract and into the left ventricle through the apex. Aortic flow was measured electromagnetically with a flow probe (Nycotron, model 376) around the ascending aorta. Left ventricular stroke volume (minus coronary flow) was determined by electronic beat-to-beat integration of the aortic flow curve. Local myocardial dimensions (segment length) were measured ultrasonically.[10] Pairs of piezoelectric crystals were inserted into the free walls of the left and right ventricles. A third pair of crystals was inserted blindly with curved needles through the left ventricle into the septum. The position of the crystals permitted recordings along the long axis of the septum.

The amplified pulses from the receiver crystals were continuously monitored on an oscilloscope. Segment length is maximal in end-diastole and is reduced during systole until end-systolic segment length is attained when aortic blood flow is reduced to zero. The difference between end-diastolic and end-systolic segment length is called systolic myocardial shortening. Any further reduction in segment length because of changes in the shape of the ventricle does not contribute to ejection and is not included in the measurement of systolic myocardial shortening. To record the septum to free wall distance, 1 ultrasonic crystal was inserted into the middle part of the septum and the other into the overlying right ventricular free wall in the inflow area.

Throughout the experiments pressures, flow, segment lengths, and the distance between the septum and the right ventricular free wall were continuously recorded on a Sanborn multichannel oscillograph.

**Experimental procedure:** After control observations, the septal artery was occluded with the snare. Recordings were continued until a new steady state had been reached during

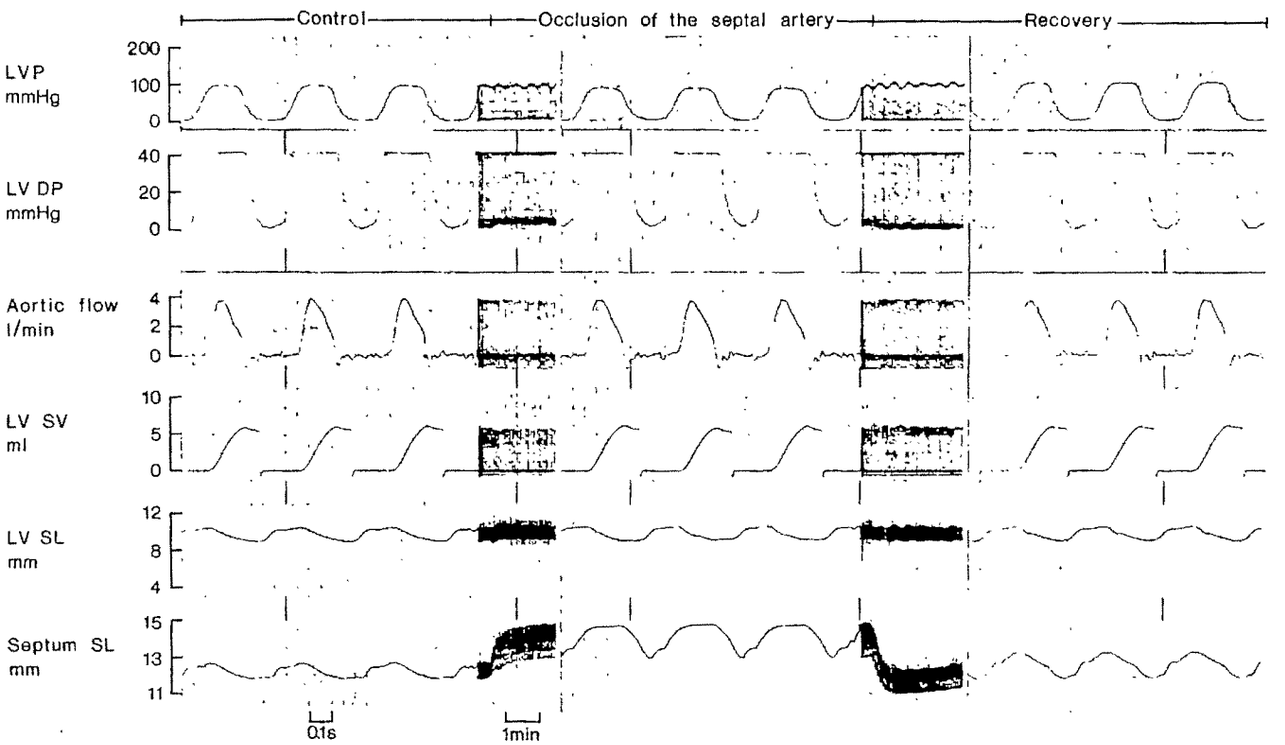

**FIGURE 1.** Hemodynamic effects of occluding the septal artery. Tracings from an experiment in a dog weighing 15 kg. LV DP = left ventricular diastolic pressure; LVP = left ventricular pressure; LV SL = left ventricular segment length (nonischemic free wall); LV SV = left ventricular stroke volume; Septum SL = septal segment length.

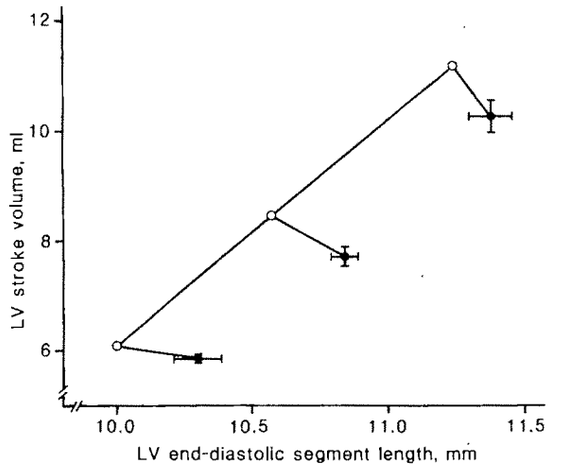

**FIGURE 2.** Relation between left ventricular (LV) stroke volume and end-diastolic segment length in the nonischemic free wall. End-diastolic segment lengths were normalized to 10.0 mm in the control period before blood volume expansion with infusion of saline solution and dextran; the individual numerical values ranged from 8.5 to 13.2 mm. **Open circles** = mean values obtained in 6 dogs (body weight 17.8 ± 2.2 kg, same dogs as in Table I) at 3 levels of blood volume when LV end-diastolic pressure increased from 3.0 ± 0.6 to 7.2 ± 1.4 mm Hg. **Closed circles** = changes (mean ± standard error of the mean) induced by occlusion of the septal artery.

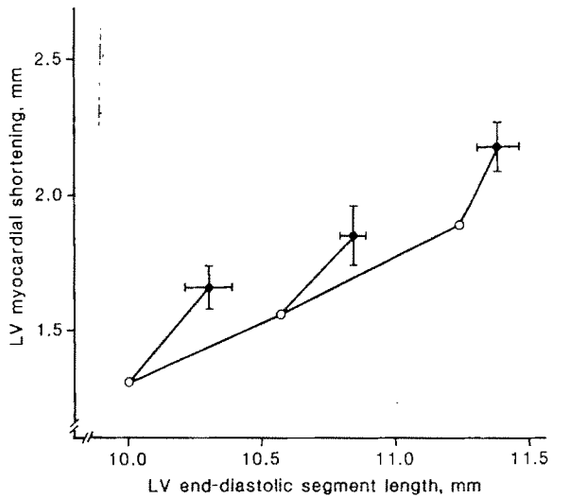

**FIGURE 3.** Relation between myocardial shortening and end-diastolic segment length in the left ventricular (LV) nonischemic free wall. **Open circles** = mean values obtained at 3 levels of blood volume. **Closed circles** = change (mean value ± standard error of the mean) induced by occlusion of the septal artery. Same dogs and experiments as in Figure 2.

septal ischemia. The duration of the ischemic period was usually 3 to 4 minutes. After release of the occlusion, the hemodynamic variables returned to control levels in 1 to 2 minutes. Occlusion of the septal artery was repeated at increasing levels of blood volume expansion induced by infusion with saline solution and dextran.

After terminating the experiment, the dogs were killed and the position of the ultrasonic crystals was examined. No signs of myocardial or coronary artery injury were observed in any of the experiments.

**Statistics:** The data are expressed as mean ± standard error of the mean. Each dog served as its own control, and Wilcoxon's test for paired comparisons was used to calculate probability values.[11] A probability value $<0.05$ was regarded as statistically significant.

## Results

Occlusion of the septal artery immediately increased end-diastolic and end-systolic segment length of the septum, and a new steady state was reached within 2 to 3 minutes. Figure 1 shows tracings from 1 representative experiment. Most of the increase in segment length of the ischemic septum occurred as ventricular pressure increased during the isovolumic period. During ejection there was a small reduction in segment length (positive systolic myocardial shortening) in 3 experiments and a further dilation (negative systolic myocardial shortening) in the 3 other experiments.

Before blood volume expansion, occlusion of the septal artery increased left ventricular end-diastolic pressure from 3.0 ± 0.6 to 4.0 ± 0.6 mm Hg, but had no effect on left ventricular peak systolic and end-systolic pressure; right ventricular pressure did not change significantly. Stroke volume averaged 6.1 ± 0.5 ml before and 5.9 ± 0.5 ml during occlusion of the septal artery ($p = 0.13$). Thus, septal ischemia did not reduce systolic ventricular pressure and stroke volume before blood volume expansion.

To examine the role of the Frank-Starling mechanism in the maintenance of the stroke volume, saline solution and dextran were infused intravenously, and occlusion of the septal artery was repeated at left ventricular end-diastolic pressures averaging 4.8 ± 0.8 and 7.2 ± 1.4 mm Hg. Although 4 to 6 intermittent occlusions were undertaken in the course of 1 experiment, the recovery time did not increase. There were no signs of deterioration as judged from the segment length recordings after release of the occlusion.

In contrast to the findings before infusion with saline solution and dextran, stroke volume decreased during occlusion of the septal artery by 9.3 ± 2.2% and 7.5 ± 2.1% at the 2 levels of blood volume expansion. Figure 2 illustrates that the reduction in stroke volume during occlusion of the septal artery was associated with a compensatory increase in left ventricular end-diastolic segment length.

Occlusion of the septal artery was associated with a marked increase in myocardial shortening of the free wall of the left ventricle (Fig. 3). The increase in myocardial shortening was similar at all levels of ventricular expansion and averaged 25 ± 8% of control values.

To further examine the change in ventricular dynamics, we compared the response to occlusion of the septal artery and the response to infusion with saline solution and dextran at similar end-diastolic segment lengths of the free wall of the left ventricle. The results of experiments in 6 dogs are summarized in Table I. Although stroke volume decreased, end-systolic segment length was significantly smaller and myocardial shortening accordingly larger in the free wall of the left ventricle during occlusion of the septal artery than during blood volume expansion. Despite the difference in end-systolic dimensions, the end-systolic pressure

was the same during the 2 procedures. In the right ventricle, myocardial shortening and end-diastolic segment length did not differ significantly during occlusion of the septal artery and blood volume expansion. Hence the free wall of the right ventricle did not participate in the compensatory response.

This observation together with increased myocardial shortening of the free wall of the left ventricle was compatible with paradoxical movement of the septum. This possibility was examined in 2 supplementary experiments by measuring the distance between the septum and the right ventricular wall. Occlusion of the septal artery had no significant effect on the end-diastolic distance but reduced the end-systolic distance as expected for paradoxical movement of the septum. Figure 4 shows tracing from 1 of the experiments, and Figure 5 shows that the systolic excursions during occlusion of the septal artery increased at all levels of ventricular expansion.

## Discussion

This study shows that acute occlusion of the septal artery in dogs immediately leads to deterioration of contractility of the septum. At a low level of blood volume expansion there is no reduction in stroke volume, partly because of increased activation of the Frank-Starling mechanism in the uninjured left ventricular myocardium. Our data also suggest that paradoxical movement of the ischemic septum compensates to some extent for the normal function of the septum in the emptying of the right ventricle.

**Septum:** After occlusion of the septal artery, the septum immediately attains an ischemic pattern with loss of contractility. This pattern is the same as observed during ischemia of the free ventricular wall.[6,7,10,12] Most of the dilation occurred during the isovolumic period. There was no significant reduction in segment length during the ejection period. Myocardial dimensions were reduced in early diastole, but end-diastolic control values were not regained.

Because of the localization of the septum, ischemia influences the emptying of both ventricles. Normally, the septum moves toward the center of the left ventricle during systole despite a large transseptal pressure difference. A bellows function is induced because the free wall of the right ventricle moves more than the septum towards the left. When the septum becomes ischemic, it behaves in a passive fashion, and the transseptal pressure gradient may cause a paradoxical movement toward the right. The extent of the movement would depend on the degree of ischemia.

Despite marked systolic bulging, occlusion of the septal artery may not render the septum completely ischemic, since collateral blood flow from the left and right coronary artery has been demonstrated.[4,13] Fixler et al[5] measured myocardial blood flow in dogs with a microsphere technique and found that as much as 54% of the blood flow to the septum remained afer ligation of the septal artery. In our study, occlusion of the septal artery probably led to a more profound reduction in blood supply. By occlusion of the left anterior descending coronary artery, 40% of the myocardial shortening may remain in the ischemic area despite the reduction in myocardial blood flow to 20% of control values.[12] Provided the nutritional requirements of the left ventricular free wall and septum are similar, the remaining blood flow to the septum should be <20% of control value since no significant myocardial shortening remained. In our study ischemic changes in the septum were reversible, and there were no signs of progressive deterioration of myocardial function in the course of several ischemic periods of 3 to 4 minutes' duration. Except for a few irregular beats immediately after occlusion of the septal artery (probably mechanically induced), no arrhythmia or conduction disturbance was observed. Evidently, longer periods of septal ischemia are required to produce arrhythmia.[3]

**Left ventricle:** Occlusion of the septal artery reduced stroke volume only after blood volume expansion, suggesting compensatory activation of the Frank-

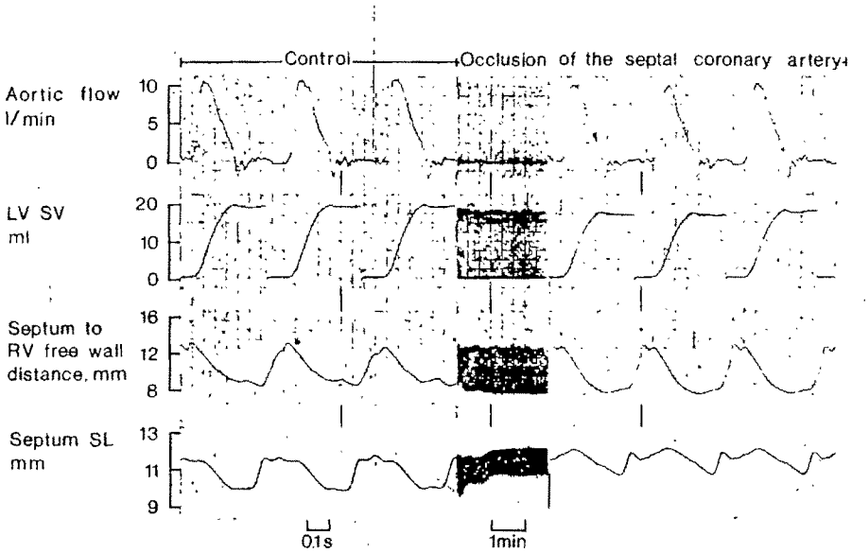

**FIGURE 4.** Effects of occluding the septal artery on the distance from the septum to the right ventricular (RV) free wall. Tracings from an experiment in a dog weighing 16 kg. LV SV = left ventricular stroke volume; Septum SL = septal segment length.

Starling mechanism after septal ischemia. The Frank-Starling mechanism, characterized by increased end-diastolic segment length and myocardial shortening, is operative up to left ventricular end-diastolic pressures of 12 to 15 mm Hg, but the response to a constant stimulus such as infusion of a certain amount of saline solution decreases as end-diastolic pressure is increased.[9] Similarly, occlusion of the septal artery might activate the Frank-Starling mechanism more at low than at high end-diastolic pressures. An interesting observation was that septal ischemia consistently modified the dynamic response of the free wall of the left ventricle. An increase in preload is usually associated with an increase in afterload because the ventricle dilates and end-systolic wall tension increases. Therefore, blood volume expansion results in increased end-diastolic and end-systolic dimensions. An isolated papillary muscle exposed to constant afterload contracts to the same end-systolic length when the end-diastolic length is varied over a wide range.[14] During occlusion of the septal artery, the nonischemic myocardium of the left ventricle contracted to the same end-systolic length as before occlusion. Thus, the intact myocardium behaved as the isolated muscle, suggesting no increase in left ventricular afterload after occlusion of the septal artery.

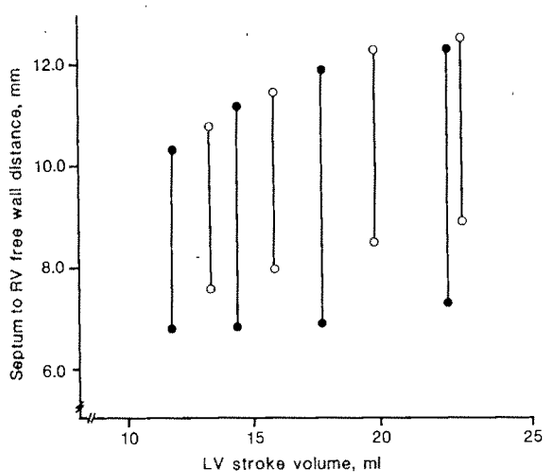

**FIGURE 5.** Relation between the distance from the septum to the right ventricular (RV) free wall and left ventricular (LV) stroke volume. Measurements were performed at 4 levels of blood volume. **Open circles** = control; **closed circles** = occlusion of the septal artery. The **vertical lines** connecting end-diastolic and end-systolic distances are systolic excursions which increased with occlusion of the septal artery.

The sequence of events may be that septal ischemia reduces stroke volume because a fraction of the ventricular blood volume is displaced toward the bulging ischemic septum rather than ejected through the aortic orifice. Myocardial shortening in the nonischemic area proceeded to the same end-systolic segment length as before occlusion of the septal artery. Comparisons at similar end-diastolic segment lengths during occlusion of the septal artery and expansion of the blood volume show that left ventricular contraction stopped at an end-systolic pressure of about 70 mm Hg but at widely different end-systolic dimensions (Table I).

**Right ventricle:** The dynamics of the free wall of the right ventricle were not changed by occlusion of the septal artery. In contrast, blood volume expansion was associated with proportional increments in end-diastolic segment length and myocardial shortening at all sites of recordings.[15] Unaltered dynamics of the free wall of the right ventricle and no reduction in stroke volume before blood volume expansion despite marked septal ischemia strongly suggest another compensatory mechanism. In addition to the ischemic contraction pattern of the septum, further evidence for bulging of the ischemic septum into the right ventricular cavity was provided by measurements of the distance between the septum and the right ventricular free wall. Increased systolic excursion to a smaller end-systolic distance than before occlusion of the septal artery strongly suggests

that the ischemic septum behaves as a passive diaphragm pump. This paradoxical movement may to some extent replace the normal contraction of the septum in right ventricular pump function.

Fixler et al[5] were first to claim that they had detected changes in right ventricular function during septal ischemia. In their study stroke volume was not reduced, and they found a reduction in systolic right ventricular pressure from 28 to 25 mm Hg. They attributed this small decrease in systolic pressure to reduced right ventricular contractility, but reduced pulmonary vascular resistance is an equally acceptable explanation since stroke volume did not decrease. To our knowledge, a reduction in stroke volume during occlusion of the septal artery has not previously been observed.

**Clinical considerations:** In man, ischemia of the septal region is usually associated with ischemia of the free walls in which systolic bulging would only have a deleterious effect. However, in principle, septal ischemia may elicit similar compensatory mechanisms in dog and man. Lesions of the left anterior descending coronary artery which reduce the blood supply to the septum either reduce septal excursion during systole or induce a paradoxical movement of the septum. This has been shown in several ventriculocardiographic and echocardiographic observations in patients with coronary artery disease.[16,17] It should be noted that the function of the ischemic septum as a diaphragm pump may be transitory because the distensibility of the septum changes during development of infarction. However, as long as paradoxical movement of the ischemic septum persists, it would support right ventricular emptying.

**Conclusion:** Our study shows that septal ischemia alters the dynamics of both ventricles. Stroke volume was not significantly reduced by occlusion of the septal artery in the unexpanded heart of a dog. Because of increased compliance of the ischemic septum, end-diastolic dilation of the left ventricle is not associated with an increase in afterload counteracting contraction. The compensatory effects of the Frank-Starling mechanism can therefore be fully exploited. However, even at moderate degrees of blood volume expansion this salutary function of the uninjured myocardium becomes insufficient and stroke volume decreases. In the right ventricle, paradoxical movement of the ischemic septum would contribute to the ejection, explaining why no compensatory changes are induced in the free wall of the right ventricle.

# Mechanisms of Spontaneous and Induced Ventricular Arrhythmias in the 24-Hour Infarcted Dog Heart

BENJAMIN J. SCHERLAG, PhD, GLENN KABELL, PhD, JOHANNES BRACHMANN, MD, LURA HARRISON, PhD, and RALPH LAZZARA, MD

**The incidence and types of ventricular arrhythmias were evaluated in 14 dogs, 24 hours after occlusion of the left anterior descending coronary artery. After induction of anesthesia and left thoracotomy, standard electrocardiographic leads and electrograms from the His bundle and the left ventricular endocardium and epicardium (both infarct and normal zones) were recorded. Spontaneous ventricular tachycardia presumably due to abnormal automaticity was consistently observed (average rate 154 ± 26 beats/min). These arrhythmias were irregular and multiform. In this same group of dogs 3 ventricular paced beats at rates above 300 beats/min induced rapid and uniform reentrant ventricular tachycardias (average rate 345 ± 17 beats/min) that were difficult to terminate by premature beats or overdrive pacing. During this sustained ventricular tachycardia, continuous electrical activity was recorded from composite electrodes on the epicardial surface overlying the infarcted zone. Such interectopic activity was not observed during the spontaneous, automatic arrhythmias. Two of the 14 dogs showed only ventricular fibrillation in response to the provocative stimuli. These data confirm previous findings that 24 hours after acute myocardial infarction in the dog heart multiform ventricular rhythms can result from enhanced automaticity. In addition, it was found that ventricular tachycardia can be induced in the same dog heart by a standard ventricular pacing procedure. Continuous electrical activity bridging the interectopic intervals only during the latter tachycardia provides strong evidence for the reentrant basis of these induced arrhythmias. These experimental findings are comparable to the 2 different forms of ventricular arrhythmias described clinically, at the same stage of myocardial infarction. The direct myocardial recordings also provide new insights into the phenomenon of entrainment of tachyarrhythmias by overdrive pacing.**

Previous studies have described various phases of ventricular ectopy occurring after the onset of myocardial ischemia and infarction in the dog heart.[1–4] Evidence compiled from experiments in vivo and in vitro indicates that the spontaneous ventricular ectopic beats and ventricular tachycardias seen in dogs 24 to 48 hours after coronary artery occlusion are primarily due to abnormal automaticity.[3,5–7] In the present study 2 different forms of ventricular tachycardia were found in the 24-hour infarcted dog heart; the mechanism of tachycardia—either abnormal automaticity or reentry—could be determined by rate, QRS morphology, and direct recordings from the myocardium. Moreover, through attempts to terminate the rapid, reentrant ventricular tachycardias with overdrive pacing, the direct recordings provided new evidence on the phenomenon of entrainment described in recent experimental[8] and clinical reports.[9,10]

## Methods

Experiments were performed in 14 adult mongrel dogs weighing 10 to 20 kg. Each was anesthetized with intravenously administered sodium pentobarbital, 30 mg/kg. Under controlled ventilation, thoracotomy was performed in the fourth intercostal space and the left atrium reflected in order to dissect the proximal left anterior descending coronary artery from the epicardial surface of the heart. The artery was ligated distal to the anterior septal branch by silk sutures passed around it and subsequently tied in 2 stages as described by Harris.[2] After repair of the thoracotomy, the animals were allowed to recover for 24 hours.

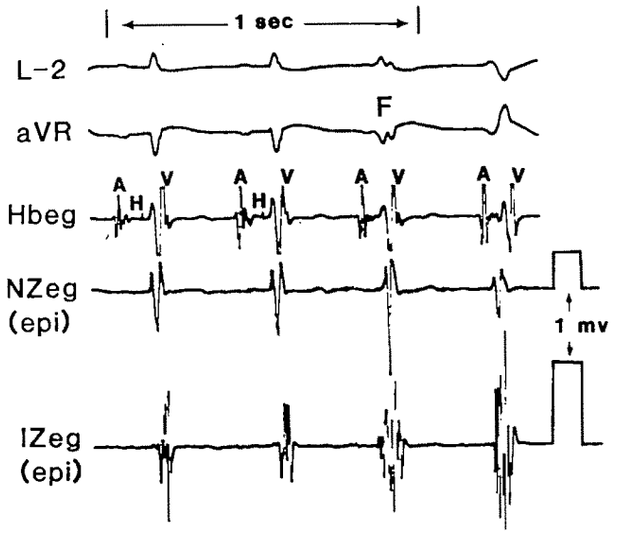

**FIGURE 1.** Spontaneous occurrence of ectopic beats in the 24-hour infarcted dog heart. Traces are lead II (L-2) and aVR electrocardiograms; His bundle electrogram (Hbeg); and composite electrogram from the normal zone of the posterior left ventricular epicardium (NZeg) and anterior epicardium overlying the infarct zone (IZeg). The first 2 beats are sinus beats and the last 2 are a fusion beat (F) and a ventricular ectopic beat. Note the disappearance of His bundle potential (H). Also the IZ composite electrogram shows various fractionated potentials but no delayed activity beyond the QRS complex.

Twenty-four hours later, after induction of anesthesia with sodium pentobarbital, standard electrocardiographic leads I through $V_6$ were monitored and transmural myocardial infarction was confirmed by the presence of Q-S patterns in the anterolateral precordial leads, mainly $V_2$ through $V_6$. The left thoracotomy incision was reopened and the pericardium split to expose the left atrium and ventricle. A large multipolar composite electrode[11] was placed over the epicardial surface of the infarct zone (anteroapical wall) and held in place by the overlying pericardium. A similar composite electrode was positioned on the posterior wall to record from the normal, noninfarcted portion of the left ventricle. Another electrode catheter passed through a carotid artery was positioned by electrographic monitoring on the endocardial surface in the infarct zone. This was determined by the marked diminution or fractionation, or both, of the electrograms recorded at this site in comparison with the normal appearance of electrograms: high amplitude, nonfractionated, within a few millimeters of this site.

A common carotid artery was exposed in the neck and a 5 or 6Fr electrode catheter with ring electrodes 10 mm apart was advanced into the aortic root to record His bundle activity.[12] Vagal-induced slowing of the heart rate was utilized to unmask underlying ventricular automaticity. This was accomplished by delivery of 0.05 ms square wave pulses at 1 to 20 V at a frequency of 20 Hz through silver wires inserted into the cervical vagosympathetic trunks.[13] Electrocardiographic leads II and aVR were monitored continuously as was arterial blood pressure. Atrial and ventricular pacing was achieved by the use of an S-88 Grass stimulator and SIU-5 isolation unit. The stimulator output delivered pulses of 2 to 10 V amplitude and 2 ms duration through stainless steel wires (0.005 in diameter) inserted into the left atrial appendage for atrial pacing or into the right ventricular myocardium near the pulmonary conus for ventricular pacing.

All records were obtained on a multichannel oscilloscopic-photographic recorder (Electronics for Medicine VR-12) at paper speeds of 25 to 200 mm/s with filter frequencies of direct current to 250 Hz for electrocardiographic leads and 30 to 250 Hz for electrographic recordings. In addition, continuous recordings were made in each experiment on a multichannel magnetic tape recorder (Hewlett-Packard 8-channel) so that selected sections could be replayed and photographed at paper speeds as high as 500 mm/s for detailed analysis. Measurements were accurate up to ±5 ms at 100 mm/s, ±3 ms at 200 mm/s, and ±1.0 ms at 500 mm/s.

**Procedure:** Recordings were obtained during sinus rhythm. Vagal-induced slowing of the sinus pacemaker was used to determine the rate and morphology of underlying ventricular ectopic pacemakers. Initially, regular pacing, at rates up to those at which Wenckebach periodicity occurred, was used to induce ventricular arrhythmias. In addition, long-short cycles of atrial paced beats[14] as well as ventricular pacing were used in an attempt to induce repetitive ventricular responses, namely, sustained ventricular tachycardia. Ventricular pacing consisted of 3 paced beats introduced during sinus rhythm at pacing rates of 300 to 420 beats/min. Sustained ventricular

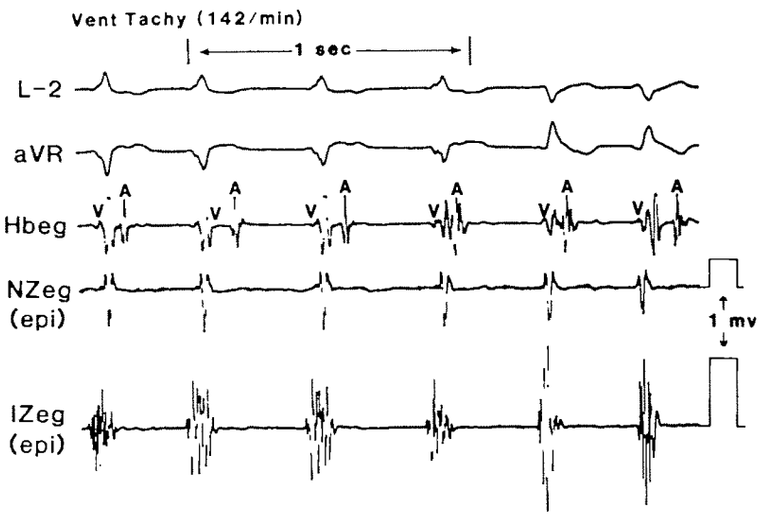

**FIGURE 2.** Spontaneous ventricular tachycardia (Vent Tachy) (approximately 142 beats/min) in the 24-hour infarcted dog heart. Traces and abbreviations are the same as in Figure 1. All the beats are ventricular ectopic in origin. Note the irregular rate and morphology of the ventricular tachycardia. As in Figure 1, the fractionated potentials are confined to the duration of the QRS and are seen only in the electrogram from the epicardium overlying the infarct zone (IZeg).

tachycardia was defined as ≥100 consecutive ectopic beats. During these pacing procedures, areas of maximal epicardial delay or diminished amplitude were sought within the infarct zone by changing the position of the composite electrode on the anteroapical wall.

## Results

In the 14 dogs studied 24 hours after coronary artery ligation, 2 distinct types of ventricular arrhythmias were consistently noted. One type of ventricular arrhythmia could be characterized as multiform ventricular rhythms at an average rate of 154 ± 26 beats/min. The ventricular beats appeared as fusion beats (Fig. 1) or were seen more commonly in the form of runs of ventricular tachycardia which were intermittent and displayed varying QRS morphologies. In order to determine the rate of the ventricular rhythm, vagal-induced slowing or arrest of the sinus rate was achieved over a period of 30 seconds to 1 minute, during which time ventricular ectopic beats were easily identified without interference of the sinus rate. Figure 1 shows 2 sinus beats with His bundle potentials (H) preceding ventricular activation (V). The last 2 beats are either fusion (F) or ventricular in origin.

The multiform nature of the observed ventricular rhythms is characterized in Figure 2. Note that during each different QRS morphology a His bundle deflection cannot be identified before ventricular activation. Also, ventricular activation in all electrograms was coincident with the QRS complex of that beat. Marked fractionation of the electrograms beyond the QRS complex was not observed.

The second type of ventricular arrhythmia was induced by 3 ventricular paced beats at rates between 300 and 420 beats/min. In the same dog as shown in Figures 1 and 2, 24 hours after coronary artery occlusion, sustained ventricular tachycardia was induced by 3 ventricular paced beats (stimuli 1, 2, and 3) at a rate of 360 beats/min. Note that in the first 2 ectopic beats preceding ventricular pacing, electrograms from the epicardium overlying the infarct zone (IZeg) are similar to those seen in the composite recordings shown in Figures 1 and 2. These electrogams show some degree of fractionation as compared with the composite electrogram over the normal zone (NZeg), but activation is confined to the duration of the QRS complex seen in leads II (L-2) and aVR. However during 3 ventricular paced beats (Fig. 3), the duration of ventricular activation increased markedly so that after the second and third beats, electrical activation in the subepicardium overlying the infarct zone extends into the S-T and T wave. At such time ventricular tachycardia at a rate of 360 beats/min was reproducibly induced. Note that during the sustained ventricular tachycardia a pattern of

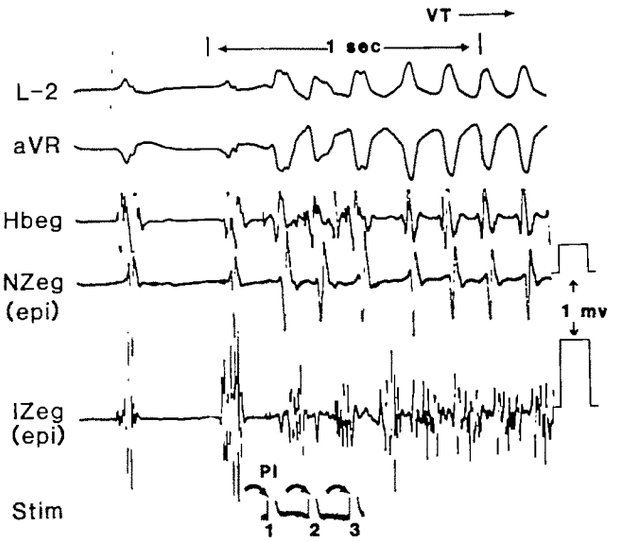

**FIGURE 3.** Induction of sustained ventricular tachycardia (VT) in the 24-hour infarcted dog heart. Traces are the same as in previous figures except for the bottom trace, which depicts stimuli (Stim) delivered to the ventricles to induce ventricular tachycardia. After 2 spontaneous ventricular ectopic beats, 3 ventricular paced beats at a rate of 360 beats/min induce a regular sustained ventricular tachycardia. Note the change in the composite recording from the IZeg, which shows continuous electrical activity during the ventricular tachycardia compared with that seen during the first ectopic beats. Note the lack of continuous activity in other leads during the induced tachycardia. Abbreviations as before.

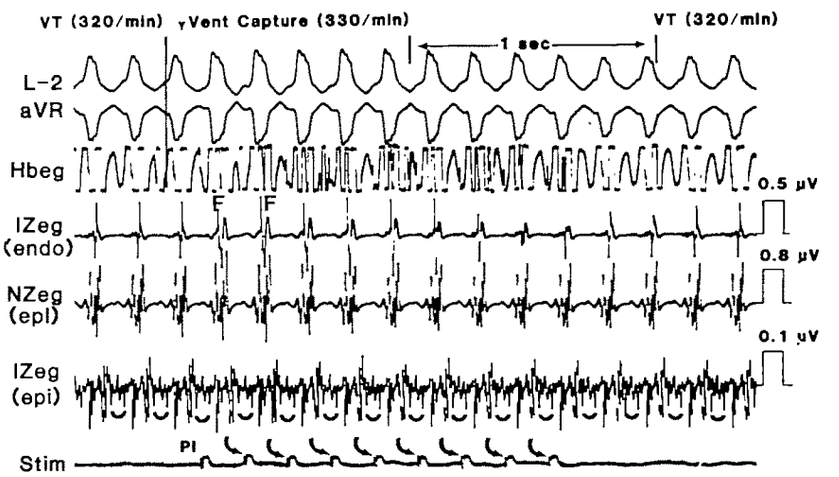

**FIGURE 4.** Overdrive pacing of sustained ventricular tachycardia (VT). Traces are the same as in Figure 3 except that the endocardial catheter recording in the area of the infarct zone (IZeg [endo]) is also shown. Ventricular (Vent) capture (**arrowhead**) by pacer impulses (PI) alters the rate (330 beats/min) and QRS morphology of the sustained ventricular tachycardia (rate 320 beats/min). Fusion beats (F) are shown in the endocardial electrograms. In the epicardial infarct zone (IZeg [epi]) no capture of the continuous electrical activity (**brackets**) occurs by the overdrive pacing, as indicated by its unchanged pattern. With cessation of pacing the sustained tachycardia continues. Abbreviations as before.

continuous electrical activity was recorded in the infarct zone electrogram but not in the normal zone electrogram.

Sustained ventricular tachycardia was induced in 12 of the 14 dogs. These sustained ventricular tachycardias were difficult to terminate using 1 or more ventricular paced beats at a rate faster than the induced tachycardia. In 8 cases it was not possible to terminate the induced sustained ventricular tachycardia by pacing, even though "capture of the QRS" was obtained. These were cardioverted by direct-current shock including 2 cases in which overdrive led to ventricular fibrillation. In the other 4 cases termination was possible with overdrive pacing. In 2 dogs ventricular fibrillation developed in response to 3 paced beats at rates between 300 to 420 beats/min rather than sustained ventricular tachycardia.

Figure 4 shows a sustained ventricular tachycardia (rate 320 beats/min) in which a reproducible pattern of continuous electrical activity was recorded only in the composite electrogram overlying the infarcted myocardium. Ventricular pacing (330 beats/min) from the right ventricular outflow tract caused ventricular capture as evidenced by the more rapid upstroke and greater amplitude of the QRS complex in both leads. Also, the electrogram from the endocardial electrode in the area of the infarct was similarly altered. However, no change in the pattern of continuous electrical activity was seen in the infarct zone electrogram. The lack of capture in the infarct zone allowed the ventricular tachycardia to continue on cessation of ventricular pacing.

However, Figure 5 shows the ability of overdrive pacing to alter the interectopic pattern without terminating tachycardia. Initially, sustained ventricular tachycardia was observed with a relatively reproducible pattern of continuous electrical activity during the interectopic intervals. After the third beat, pacing impulses (PI, curved arrows) were delivered to the ventricle at a faster rate (400 beats/min) than the spontaneous tachycardia (360 beats/min). Note that although the major portion of the ventricles has been captured, resulting in a changed QRS complex (vertical arrow) and alteration of the normal zone electrogram, the pattern of continuous electrical activation in the area overlying the infarct zone is only partly altered. The negative potential (slanted arrows), which was consistently activated at the end of the interectopic interval, just before the onset of the QRS complex is, during pacing, activated at various times within the interectopic interval. Note the changing relation of this potential (straight arrow) to the pacing impulse (PI, curved arrows). When ventricular pacing ceases the sustained ventricular tachycardia continues, and this negative potential resumes its previous position in the interectopic interval. Analysis of the QRS complex might support entrainment[10]; however, recordings from the epicardium in the infarct zone show that the reentrant circuit was only partly captured.

In Figure 6, after a more prolonged overdrive at 390 beats/min, the sustained ventricular tachycardia was terminated. Before termination there is capture of the entire heart including the reentrant circuit, but a different pattern of continuous activity is seen during the interectopic interval. In the trace labelled IZ eg (epi) the length of the interectopic interval is indicated with a black bar. Note that during the interval there is a progressive delay between the initial and the terminal deflections in a Wenckebach-like manner (from 53 to 75 ms). At the greatest delay the continuous activity ceases and an isoelectric period precedes each paced beat. When pacing stops the sustained ventricular tachycardia does not continue. These various forms of entrainment are discussed later.

Table I summarizes the results of this study. Spontaneous ventricular arrhythmias that were intermittent and multiform were found either during normal sinus rhythm or by slowing the sinus rate of vagosympathetic trunk stimulation. The average heart rate of these ectopic rhythms was 154 ± 26 beats/min. Continuous activity was not observed on any of the direct recordings from the ventricular surfaces. At pacing rates of 300 to

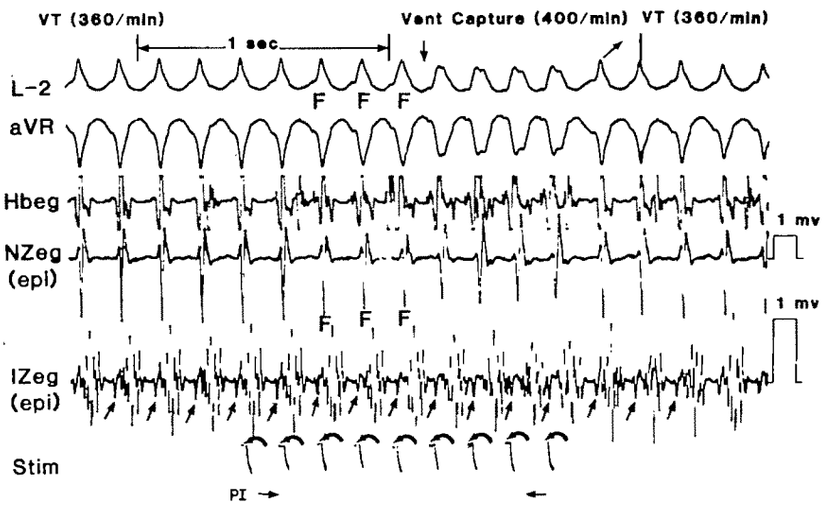

**FIGURE 5.** Attempt to terminate sustained ventricular tachycardia (VT) by ventricular pacing. In the first 6 beats there is a reproducible pattern of electrical activation that occupies most of the interectopic interval. The **slanted arrows** denote the potential that precedes each QRS complex. Ventricular pacing (400 beats/min) (PI = pacer impulse, **curved arrows**) at a rate faster than the induced ventricular tachycardia (360 beats/min) captures the ventricles (**vertical arrow**) as indicated by the change in the QRS complex after the fusion beats (F). Ventricular pacing fails to terminate the tachycardia. See text for details.

420 beats/min in 12 of 14 dogs sustained ventricular tachycardia resulted. These ventricular tachycardias are unifocal and regular at an average rate of 345 ± 17 beats/min. The difference between the average heart rates of these spontaneous and induced ventricular tachycardias was significant ($p < 0.01$). Furthermore, mean blood pressure was also significantly different during the automatic (98 ± 27) and reentrant (33 ± 18) arrhythmias ($p < 0.001$).

**TABLE I Comparisons of Automatic and Reentrant Tachycardias in the 24-Hour Infarcted Dog Heart**

| | Automatic | | Reentrant |
|---|---|---|---|
| Heart rate | 154 ± 26 | $p < 0.01$ | 345 ± 17 |
| QRS morphology | Multiform | | Uniform |
| Regularity | Irregular | | Regular, sustained |
| Mean blood pressure (mm Hg) | 98 ± 27 | $p < 0.001$ | 33 ± 18 |

## Discussion

**The 24-hour infarcted heart:** Several aspects of this experimental preparation should be emphasized. From a mechanistic viewpoint, this study shows that there are 2 distinct forms of arrhythmias seen in this setting: 1 due to abnormal automaticity and the other to a reentrant mechanism. In regard to the former, the present study confirms the previous findings of others[2–4,15] which provided evidence that multiform ventricular rhythms in the 24-hour infarcted dog heart were unmasked by vagal-induced slowing of the heart rate, easily overdriven by atrial pacing but not terminated by the paced beats. In vitro, surviving subendocardial Purkinje fibers have been found in the 24-hour infarct which showed enhanced diastolic depolarization.[5,6] This enhanced automaticity is not found in Purkinje fibers at the same sites after excision from normal hearts.[16] Some recent reports have suggested that triggered automaticity might be responsible for the abnormal automaticity seen in 24-hour infarcted hearts.[7]

The present study also demonstrates that ventricular pacing can be used to consistently induce sustained ventricular tachycardia (12 of 14 dogs). The induced tachycardias were always associated with fractionated electrical activity recorded from the subepicardium overlying the infarct. Moreover, this activity was found to form a continuous bridge between the beat initiating the tachycardia and the first ectopic beat and between subsequent ectopic beats. Although this evidence of slow conduction does not fulfill many of the previously established criteria for reentry, that is, unidirectional block and mapping of the circus movement(s), it represents strong presumptive evidence for reentry.[1,8,17–19] In this regard, electrograms taken from identical sites during the multiform ventricular rhythms never showed continuous or bridging electrical activity between ectopic beats (Fig. 1 and 2). In addition, a clear difference in the rate of the induced reentrant tachycardias and the automatic arrhythmias was observed (Table I). The former showed a regularity of rhythm and QRS morphology, whereas the latter were irregular and had multiform QRS complexes.

Previous reports have described the induction of sustained or protracted ventricular tachycardia in the 3 to 7 day infarcted dog heart.[8,20–24] The incidence of sustained ventricular tachycardia was as variable among these groups as were the techniques for producing their models of sustained ventricular tachycardia. All these reports had in common the conclusion that these tachycardias were well tolerated hemodynamically, easily induced and easily terminated by pacing, and probably caused by a reentrant mechanism. As such, the preparation of an infarcted dog heart 3 to 7 days after coronary artery occlusion[8,20,21,24] or after coronary artery occlusion and reperfusion[22,23] is similar to the patient with recurrent ventricular tachycardias.[25,26]

The 24-hour infarcted heart preparation described in the present study shows induced tachycardia which differed from those described in the subacute studies mainly by the hemodynamic and electrical instability

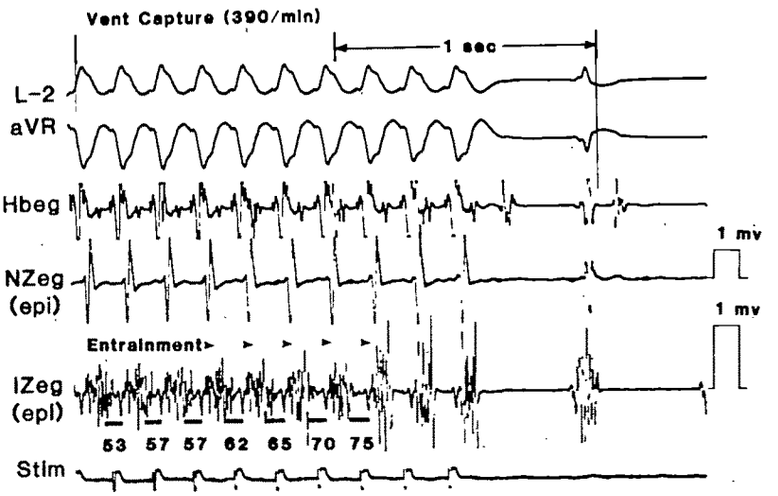

**FIGURE 6.** Successful termination of sustained ventricular tachycardia by prolonged overdrive pacing. Pacing changed the pattern of the interectopic activity (bars) compared with that seen during ventricular capture in Figure 5. During the period of entrainment the time between the initial and terminal interectopic activity (IZeg [epi]) increased from 53 to 75 ms in a Wenckebach fashion. Subsequently, an isoelectric period occurred concomitant with a change in the infarct zone electrogram. With cessation of pacing sustained tachycardia was abolished. See text for discussion. Abbreviations as before.

of the former preparation. In this respect, the sustained ventricular tachycardias induced in the 24-hour infarcted heart are similar to those induced in patients surviving out-of-hospital cardiac arrest.[27] Therefore the use of this preparation may be applicable in testing new antiarrhythmic agents against life-threatening arrhythmias in the experimental animal and eventually in the patient at risk for sudden death.

**Clinical implications:** With the advent of continuous electrocardiographic monitoring in the coronary care unit, it was found that paroxysmal ventricular tachycardia, rather than being rare, was a common occurrence in patients 24 to 48 hours after the onset of myocardial infarction. It has been reported that accelerated idioventricular rhythms occur fairly often in patients with acute myocardial infarction.[28,29] In man, these arrhythmias have been characterized by a relatively slow rate, 60 to 100 beats/min, a gradual onset, and termination with no adverse hemodynamic effect and no tendency to ventricular fibrillation. Enhanced automaticity of ectopic foci has been regarded as a primary causal mechanism because ventricular fusion beats are common. Except for the rate and multiformity, these clinical tachycardias are very similar to those occurring spontaneously in the 24-hour infarcted dog heart. The explanation for the faster rate and multiform character of the abnormal ventricular automaticity may be the high sympathetic tone in the open-chest, pentobarbital-anesthetized dog.

In contrast, Wellens et al[30] presented a series of patients studied 24 to 48 hours after acute myocardial infarction who manifested sustained ventricular tachycardias. Both atrial and ventricular paced beats failed to convert these arrhythmias to sinus rhythm. This is consistent with our findings in 24 infarcted dog hearts in which the induced ventricular tachycardias (rates averaging 345 beats/min) were interrupted only with difficulty and only after prolonged periods of overdive pacing (Fig. 4 and 5). Wellens et al[30] concluded that the ventricular tachycardias they observed were the result of an automatic mechanism because they could not be readily initiated and terminated by paced beats. However, there is no indication that the rhythms were overdriven; rather cardioversion was used to terminate the arrhythmia in 4 of the 6 patients. In only 2 of these patients could the tachycardia be terminated by 2 ventricular premature beats in close succession. In contrast to these patients with acute myocardial infarction, Wellens et al[30] found that the great majority of patients with chronic myocardial infarction, studied electrophysiologically, exhibited facile initiation and termination of tachycardias with ventricular premature or atrial premature beats.

Rothfeld et al[28] described 2 patients studied 24 to 48 hours after acute myocardial infarction. Each showed accelerated idioventricular rhythm (60 to 100 beats/min) which were intermittently interrupted by paroxysms of rapid ventricular tachycardia at rates at least 100 beats/min faster. This occurrence of 2 forms of ventricular tachycardia supposedly caused by 2 different mechanisms is closely analogous to that seen in our experimental preparation.

**Entrainment of ventricular tachycardia:** In the course of these studies several insights were made into the phenomenon of entrainment of ventricular tachycardia.[10] This process has been variously described as continuous concealed reentry,[8] concealed perpetuation,[26] and entrainment.[10] The last term has been the subject of detailed studies both in atrial[31] and ventricular tachyarrhythmias. MacLean et al[10] defined entrainment of a tachycardia by rapid pacing as "an increase in the rate of all tissue of a chamber being paced to a faster rate than the tachycardia, with resumption of the intrinsic rate upon either abrupt cessation of pacing or slowing of the pacing rate below the intrinsic rate of the tachycardia." This effect occurs within a narrow range of increased pacing rates above which the tachycardias are usually interrupted. The use of the composite electrogram in the infarct zone in the present study allowed observations not possible using electrocardiography alone. For example, our results demonstrate that entrainment of ventricular tachycardia or capture of the ventricles by pacing can occur while local electrograms in the infarct zone are unaltered in their pattern of activation (Fig. 3). Similarly, Josephson et al[9] showed transient entrainment of ventricular tachycardia during overdrive with concealed perpetuation of the intrinsic ventricular tachycardia. This was indicated by the unchanged activation of an electrogram recorded within a ventricular aneurysm during sustained ventricular tachycardia and during ventricular pacing. These investigators concluded that "the reentrant circuit must be small, electrocardiographically silent and relatively protected." MacLean et al,[10] on the other hand, proposed that transient entrainment occurs as a result of failure to achieve a critical ventricular rate. Our findings provide evidence for this view as well. In Figure 6 we showed that the pattern of continuous activity during "ventricular capture" at a rate of 390 beats/min was substantially different from the pattern during the intrinsic ventricular tachycardia at a rate of 360 beats/min (Fig. 5). That 390 beats/min was a critical rate is shown by the occurrence of a Wenckebach-like delay within the slow conducting portion of the reentrant circuit before actual capture and termination of the sustained tachycardia (last 3 paced beats in Figure 6).

In our studies the apparent protection of the reentrant circuit may be in part the result of the rapid rate of the ventricular tachycardia which leaves little interectopic time for the pacing impulse to enter the circuit, the distance from the pacing site to the area of reentry, and the small size of the reentrant circuit. A more systematic study of this phenomenon in the preparation we have decribed may provide a better understanding of entrainment of ventricular tachycardia.

In conclusion, in a preparation of myocardial infarction in the dog heart 24 hours after coronary artery occlusion, 2 types of ventricular arrhythmias can be consistently differentiated on the basis of the presence or absence of continuous electrical activity recorded from composite electrodes on the epicardial surface overlying the infarct zone. This preparation can be used

to study the mechanisms of sudden death, the effect of drugs in the prevention of life-threatening ventricular tachycardia, and the pathophysiologic mechanisms of ventricular tachycardia.

**Acknowledgment:** We thank Marrion B. Bolar and B. Jay Wasserlauf for their surgical and technical assistance. Also we acknowledge the secretarial contributions of Marie Z. Ellis, Denyvetta Davis, and Darlene Lewis in the production of this manuscript.

# INSTRUCTIONS TO AUTHORS

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY and they become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. The Publisher assumes no liability for any material published in the *Journal.* All accepted manuscripts are subject to editing to aid understanding and conserve space.

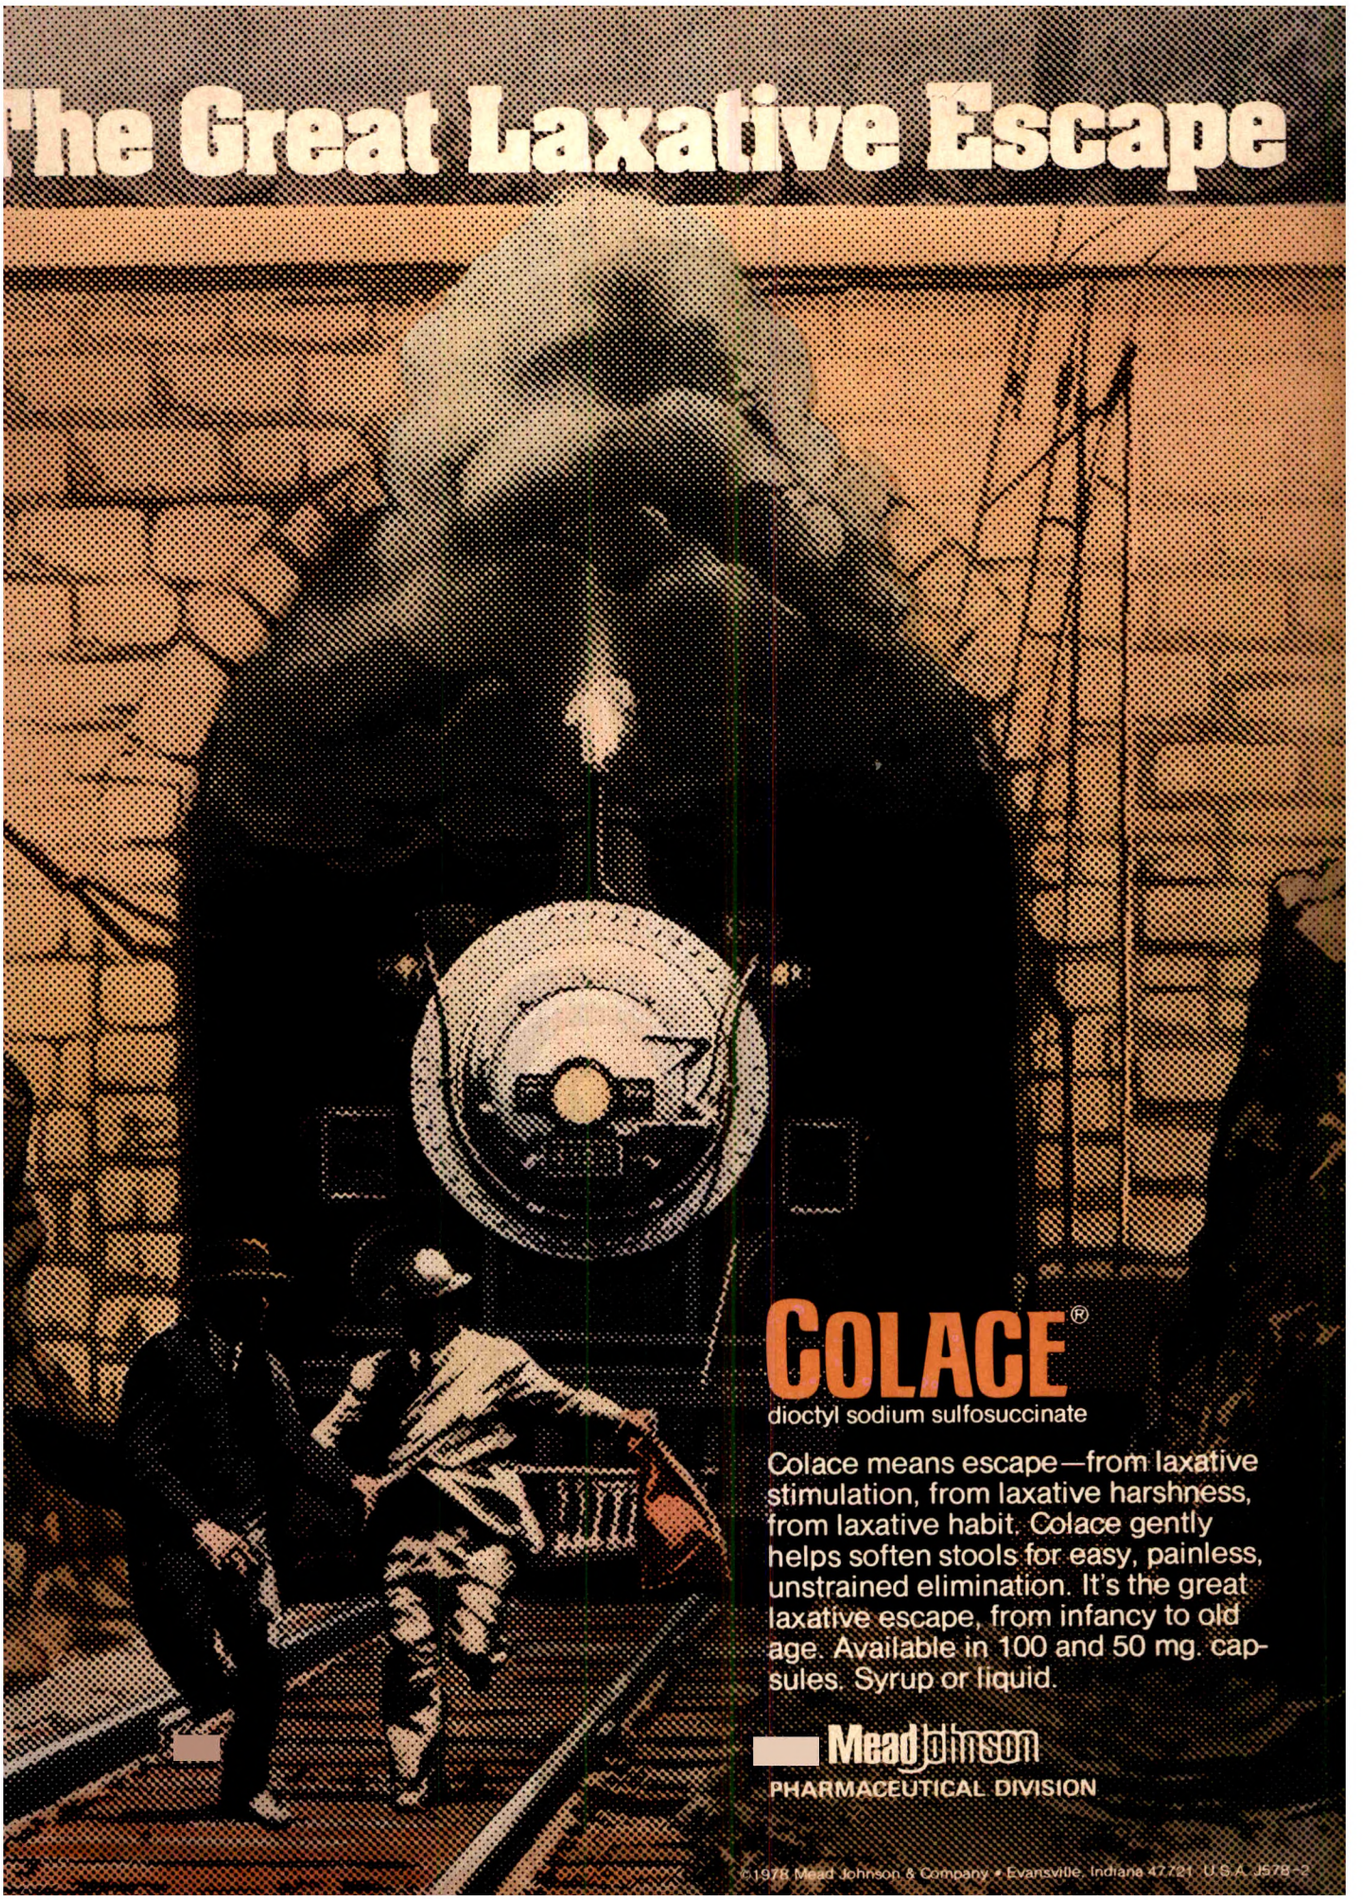
**ADDRESS MANUSCRIPTS TO:** William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 6935 Arlington Road, Suite 406, Bethesda, Maryland 20814. The *covering letter* should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make: for example, the elimination of 1 or more figures or tables or a portion of the text to increase the likelihood of publication of their work in the *Journal.* Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The suggested reviewers will be carefully considered along with other experts in the field. Additionally, the editor would listen if the authors provided the names of any investigators they consider unlikely to give nonbiased reviews of their work.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page consisting of the article's title, the names of the authors, and the institution from which the work originated, (2) a second title page including only the article's title, (3) summary, (4) text, (5) references, (6) acknowledgment, (7) figure legends, and (8) tables. Number all pages in the above sequence, beginning with the title page as 1, the summary as 2, and so on (leave the second title page unnumbered). Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25 mm (1 inch) margins.

The second title page, the one which omits the names of the authors and the institution, will permit the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be obtained. The authors may state which type of review they wish in the covering letter.

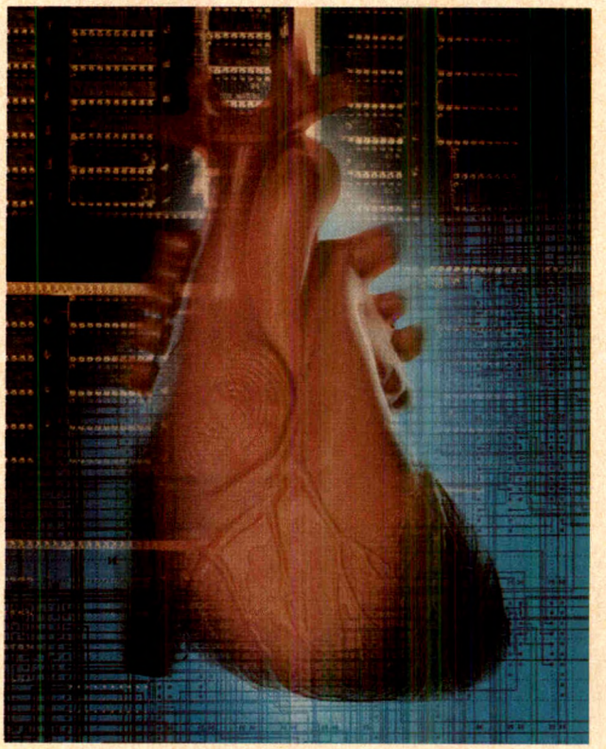
**TITLE PAGE, SUMMARY, AND ABSTRACT:** Include the first or middle and last names with other initials of all authors. Provide a short *running title* of 3 to 6 words. Insert at the bottom the name and address of the institution from which the work originated, and information about grant support if necessary. Add at the bottom the phrase "*Address for reprints:*" followed by full name and address with zip code. Limit the **summary** to 250 words. Also, submit an **abstract** of 150 words or less to be used in the Table of Contents. List 2 to 6 **key words** for subject indexing at the end of the summary.

**STYLE:** Use appropriate **subheadings** throughout the body of the text, such as in the Methods, Results, and Comments sections. **Abbreviations** are permitted, but no more than 2 or 3 per manuscript. Spell out the first time they appear in the text followed by the abbreviation in parentheses. Consult the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* published in the *Annals of Internal Medicine* June 1982; 96: 766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence.



**REFERENCES:** In references, list **all authors,** inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts if possible, but indicate by the abbreviation (*abstr*) when doing so. Do not use periods after authors' initials. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications do not constitute references. In referring to a manuscript that has been submitted but not yet published, use the phrase "unpublished observations" in parentheses.

> **Journal:** Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–1034.
>
> **Chapter in Book:** Schiebler GL, Van Mierop LHS, Krovetz LJ. Diseases of the tricuspid valve. In: Moss AJ, Adams F, eds. Heart Disease in Infants, Children and Adolescents. Baltimore: Williams & Wilkins, 1968: 134–139.
>
> **Book:** Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.



**FIGURES:** Submit 3 glossy nonmounted *prints* of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all *charts* (line drawings). Make decimals, broken lines, etc. strong enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by number and title of the article (omit the authors' names so that blinded reviews can be obtained). Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figure. Limit figures to the number necessary to present the message clearly. Type each figure legend on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author. If color figures are submitted, identify in the covering letter who should be billed for the color charges.

**TABLES:** Place each table on a separate page, double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating data on patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate positive or present; a zero (0) for negative or absent, and a dash (—) for "no information available" or "not done."

**REPRINTS:** Price schedules and order cards for reprints will be mailed to the author on publication of the article. Individual reprints must be obtained through the author.

The Great Laxative Escape
COLACE®
dioctyl sodium sulfosuccinate
Colace means escape—from laxative stimulation, from laxative harshness, from laxative habit. Colace gently helps soften stools for easy, painless, unstrained elimination. It's the great laxative escape, from infancy to old age. Available in 100 and 50 mg. capsules. Syrup or liquid.

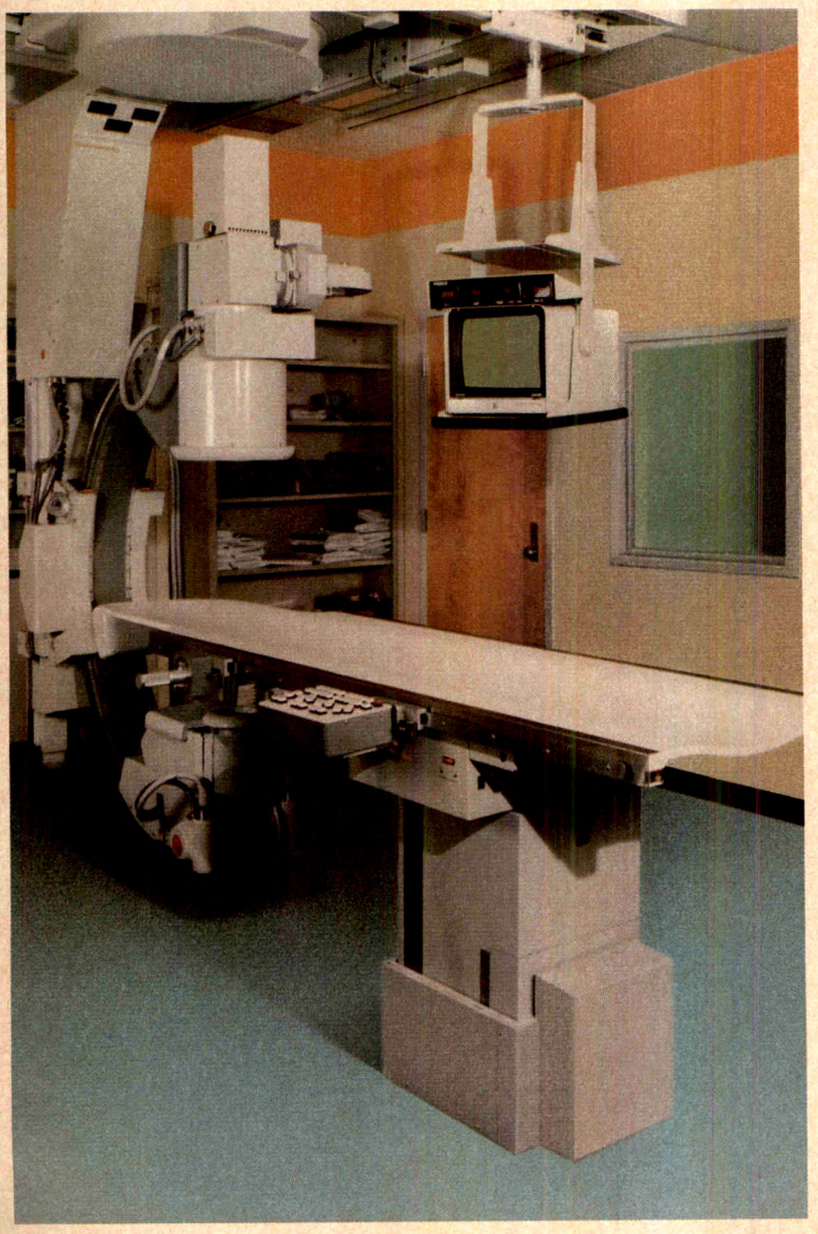
# Cardicon's microprocessor does something important for cardioangiography.

# Makes it easier.



A108

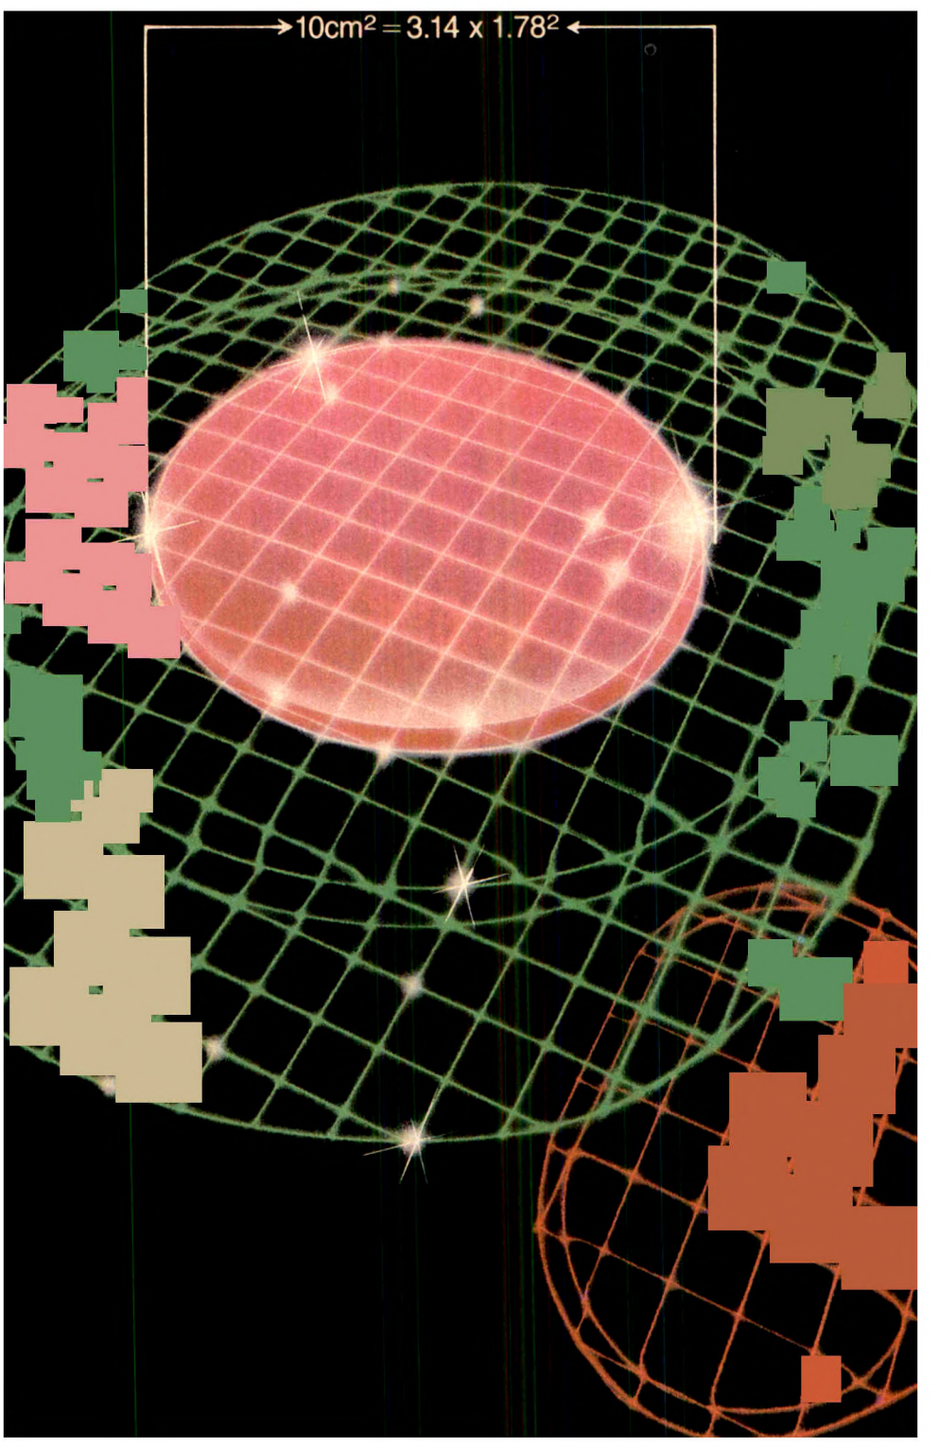
The difference is patient positioning. It's one of the key elements of cardioangiography. And now, Cardicon makes it easy.

This microprocessor-controlled, ceiling-mounted C-arm system gives you totally flexible and repeatable positioning. With digital controls. And with maximum operator convenience, right down to the adjustable-height C-arm and table.

With Cardicon, you get total patient coverage, excellent patient access. With an unlimited choice of projection angles. For complete visualization of the heart chambers and all segments of the arterial tree.

In fact, every component of the Cardicon system is totally integrated for best quality image. Like the unique Isocon camera system designed for high sensitivity, unmatched resolution, and wide dynamic range. Plus an integrated video disc and tape combination that gives you both slow motion and still frame replay for real-time diagnosis. Which simplifies your exam, decreases study time, and is easier on your technologists and your patients.

And because it's compatible with our DAS 211 digital system, Cardicon is the system you can plan on for years to come.



So find out more about the most convenient cardioangiographic system on the market. Find out about the difference Cardicon can make.

**The diagnostic difference. Now.**

10cm² = 3.14 x 1.78²

# Designed with the patient in mind.

**People move, bend, stretch, perspire.**
When we designed Nitro-Dur™ (nitroglycerin) Transdermal Infusion System, we designed it with features to accommodate these human factors. Because of the size of Nitro-Dur it has features that other nitroglycerin systems don't have.

**It's big because it's the only one with a wide adhesive strip.**
If angina patients were supine for 24 hours, adhesion would be a minor concern. But people move, bend, stretch, and turn while awake and asleep. A system has to stay put throughout all these movements.

In developing Nitro-Dur, we tested dozens of tapes before we settled on a microporous tape known for its excellent adhesion, one that doesn't leave the skin macerated and is relatively painless on removal.

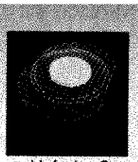
The Nitro-Dur adhesive strip is wider than that on any other system. Wide enough to stay put during a 24-hour day of walking, showering, bending, standing or sleeping. Wide enough to prevent leaking or falling off.

**It's big because it's the only one with an absorbent pad.**
Because perspiration could affect adhesion, we added an absorbent pad behind the matrix. Nitro-Dur is the only system with this feature.

**Surface area determines the dose.**
The stratum corneum regulates the absorption of cutaneously applied nitroglycerin. Therefore, as the surface area of application is increased the dose of nitroglycerin also increases. To insure a fixed surface area, we offer a solid—a gel polymer matrix that contains the active drug.

**The only transdermal to offer you greater dosage flexibility.**
Nitro-Dur has four dosage strengths—5, 10, 15 and 20 $cm^2$. Other systems limit your options to two strengths.

**The only place it's smaller—the cost to your patients.**
Your patients can save up to $75 a year using Nitro-Dur rather than competitive products. Considering that they may be taking the product for years, that's a very important advantage.[1]



The human factor made us big. You made us the largest-selling transdermal nitroglycerin system.

**The most widely prescribed transdermal nitroglycerin system.**

**Nitro-Dur™**
(nitroglycerin)
Transdermal Infusion System

Please see next page for a summary of prescribing information.

# Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

**DESCRIPTION:** The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing precise dosing levels of nitroglycerin. Nitro-Dur has a rated release *in vivo* of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

**CLINICAL PHARMACOLOGY:** When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies[2] transdermal absorption of nitroglycerin from the gel-like matrix achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Therapeutic effect is achieved within 30 minutes after application of the unit, and persists about 30 minutes after removal of the unit.

**INDICATIONS AND USAGE:** Prevention and treatment of angina pectoris due to coronary artery disease.

**CONTRAINDICATIONS:** Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

**WARNINGS:** The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

**PRECAUTIONS:** Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

**ADVERSE REACTIONS:** Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

**HOW SUPPLIED:** Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28.

**CAUTION:** Federal law prohibits dispensing without a prescription.

**PATIENT INSTRUCTIONS FOR APPLICATION:** Patient instructions are furnished with each unit dose package.

# MYOCARDIAL REVASCULARIZATION

## MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

## The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

## Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

# Critical Pattern Recognition.™
# The next wave in Holter data analysis.

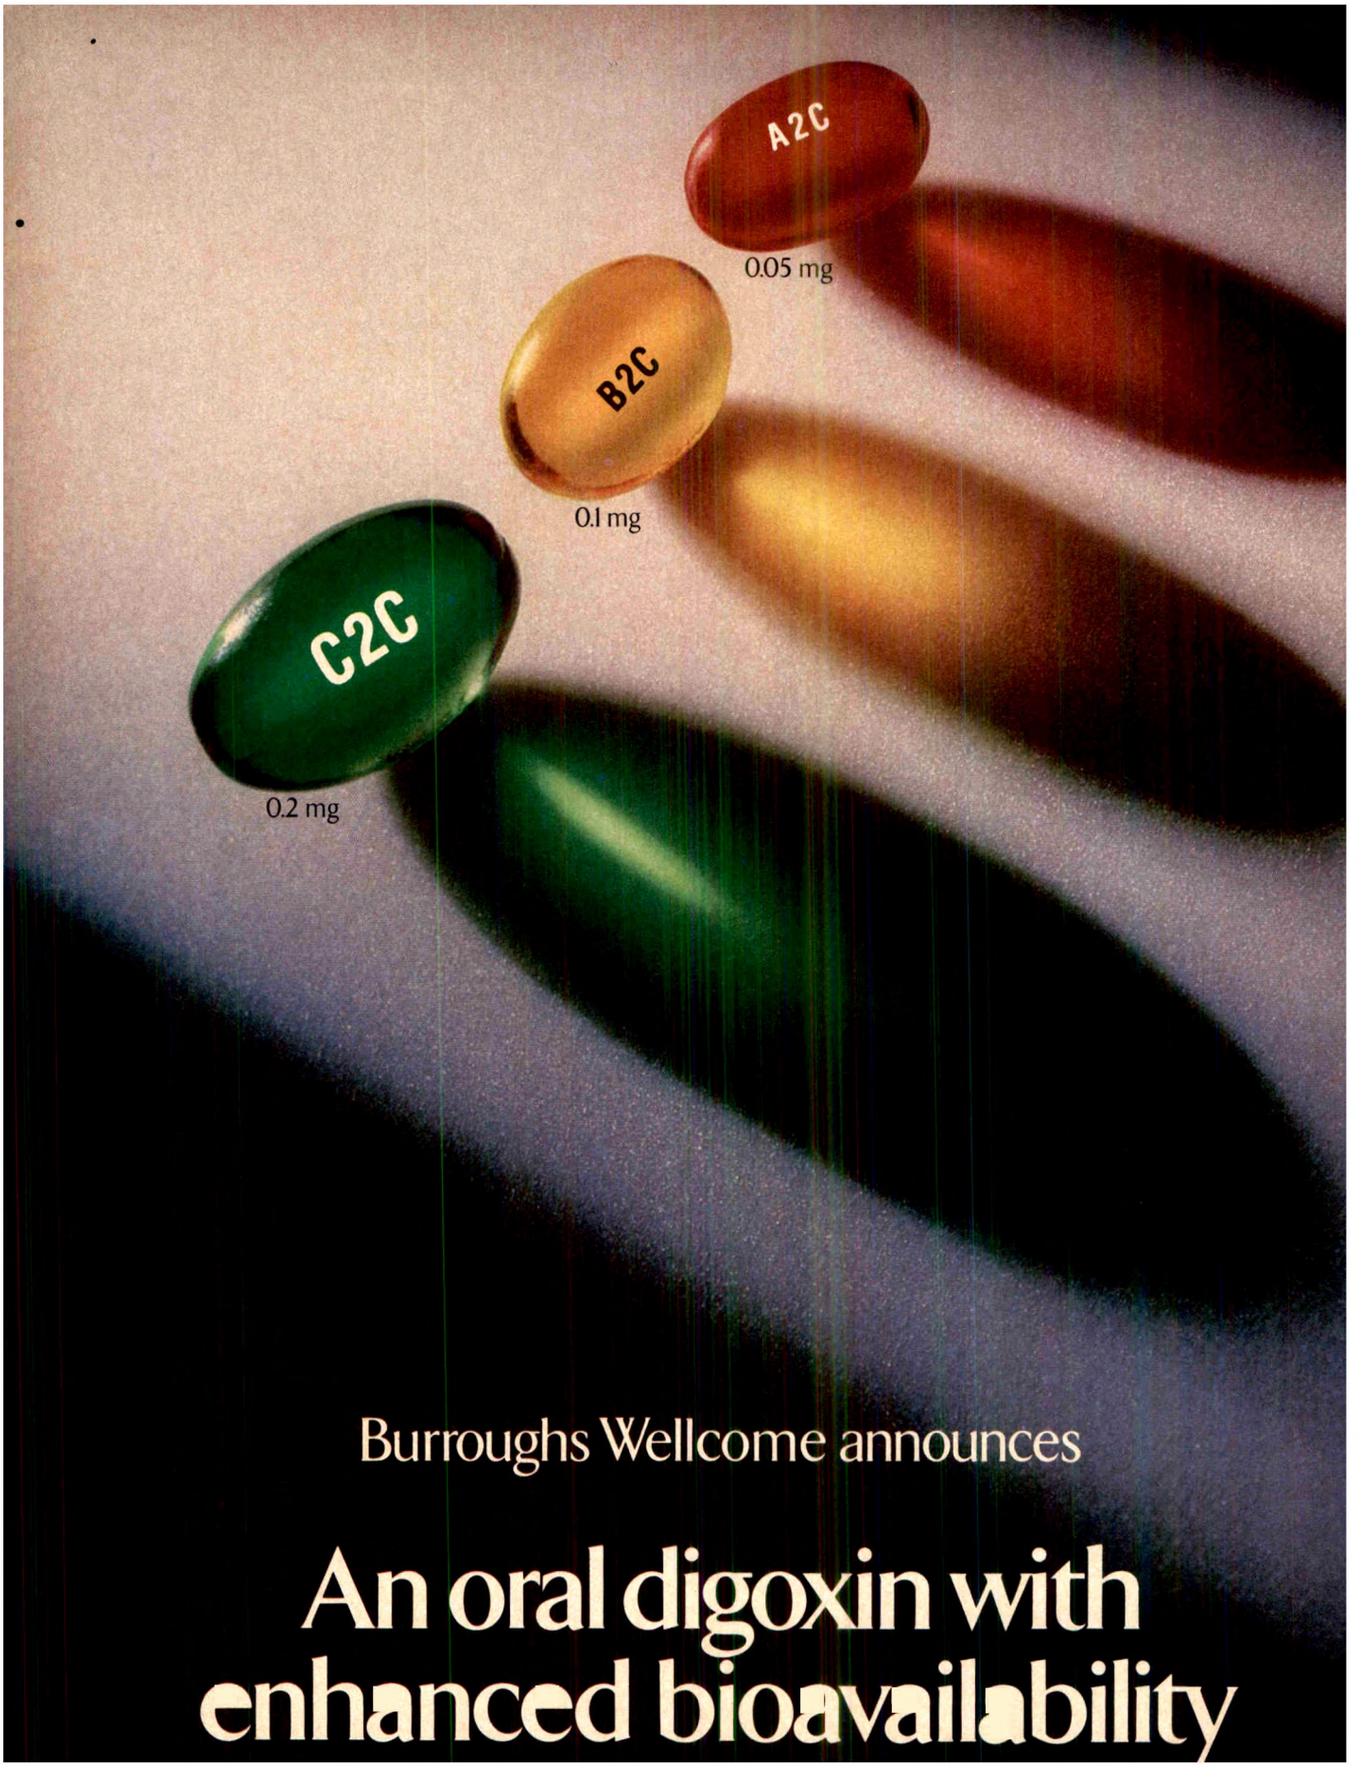
## DEL MAR AVIONICS

No two patients have exactly the same ECG waveforms.

So to give you the most precise data analyzer for processing Holter tapes, we offer Critical Pattern Recognition.

Both the Trendsetter™ and Evaluator™ Data Analysis Systems are computer-controlled to recognize normal and variant ECG waveforms for each individual patient.

Waveforms are categorized, counted and compared to the patient's typical ECG, even though these normal patterns may vary throughout the monitoring period.



Moreover, analysis is halted automatically upon occurence of significant ectopic patterns, such as paired VEs/SVEs, R-on-T, V-Tach, SV-Tach, Ventricular Bigeminy, Bradycardia beats/runs and other critical events.

Dual 12-in CRT displays provide unsurpassed control of real-time data. And a wide selection of report formats (alphanumerics, graphics and analog trends) provide comprehensive permanent data for improved patient management.

Additionally, the Trendsetter can be updated to accommodate blood pressure, pacemaker analysis, dual floppy disks and other options. Choose only what you need now and add more capability later.

For more details on the first Holter data analysis systems to offer Critical Pattern Recognition, call or write: Del Mar Avionics, 1601 Alton Avenue, Irvine, California 92714, Telephone (714) 549-1500, or call toll free at (800) 854-0481, (in California 800/432-8446), Telex: 68-5621.

Burroughs Wellcome announces

# An oral digoxin with enhanced bioavailability

# Absorption of digoxin from LANOXICAPS® is 90-100% complete!

The enhanced digoxin absorption from LANOXICAPS® compared to tablets and elixir is associated with reduced between-patient and within-patient variability in steady-state serum concentrations.

| Comparison of bioavailability and equivalent doses | | | | |
|---|---|---|---|---|
| Product | Bioavailability | Equivalent Doses (in MG)* | | |
| Lanoxin® Tablet | 60-80% | 0.125 | 0.25 | 0.5 |
| Lanoxin® Elixir | 70-85% | 0.125 | 0.25 | 0.5 |
| Lanoxin® Injection/IM | 70-85% | 0.125 | 0.25 | 0.5 |
| Lanoxin® Injection/IV | 100% | 0.1 | 0.2 | 0.4 |
| **LANOXICAPS®** Capsules | 90-100% | 0.1 | 0.2 | 0.4 |

*1 mg = 1,000 μg

Due to the more complete absorption of digoxin from Lanoxicaps, recommended oral doses are 80% of those for tablets, elixir, and IM injection.

Lanoxicaps may help make a smoother transition for patients who are being switched from intravenous to oral therapy. Also, consider Lanoxicaps for all your newly diagnosed patients.

Colors of Lanoxicaps are distinctive, for less confusion or misidentification by patients. Please see next page for brief summary of prescribing information.

**LANOXICAPS®** brand DIGOXIN SOLUTION IN CAPSULES 50 μg (0.05 mg), 100 μg (0.10 mg), and 200 μg (0.20 mg)
*Brief Summary of Prescribing Information*

**INDICATIONS AND USAGE**
**Heart Failure:** The increased cardiac output resulting from the inotropic action of digoxin ameliorates the disturbances characteristic of heart failure (venous congestion, edema, dyspnea, orthopnea and cardiac asthma).

Digoxin is more effective in "low output" (pump) failure than in "high output" heart failure secondary to arteriovenous fistula, anemia, infection or hyperthyroidism.

Digoxin is usually continued after failure is controlled, unless some known precipitating factor is corrected. Studies have shown, however, that even though hemodynamic effects can be demonstrated in almost all patients, corresponding improvement in the signs and symptoms of heart failure is not necessarily apparent. Therefore, in patients in whom digoxin may be difficult to regulate, or in whom the risk of toxicity may be great (e.g., patients with unstable renal function or whose potassium levels tend to fluctuate) a cautious withdrawal of digoxin may be considered. If digoxin is discontinued, the patient should be regularly monitored for clinical evidence of recurrent heart failure.

**CONTRAINDICATIONS**
Digitalis glycosides are contraindicated in ventricular fibrillation.

Any untoward effect requiring permanent discontinuation of other digitalis preparations usually constitutes a contraindication to digoxin, as is hypersensitivity to digoxin itself. Allergy to digoxin, though rare, does occur. It may not extend to all preparations, and another digitalis glycoside may be tried with caution.

**WARNINGS**
The use of digoxin or other digitalis glycosides is unwarranted in the treatment of obesity.

Digoxin in soft capsules should be administered in divided daily doses to minimize any potential adverse reactions. Where compliance is considered a problem, single daily dosing may be appropriate.

Anorexia, nausea, vomiting, and arrhythmias may accompany heart failure or may be indications of digitalis intoxication. Clinical evaluation of the cause of these symptoms should be attempted before further digitalis administration.

Patients with renal insufficiency require smaller than usual maintenance doses of digoxin (see DOSAGE AND ADMINISTRATION section in complete prescribing information).

Heart failure accompanying acute glomerulonephritis requires extreme care in digitalization. Low loading and maintenance doses and concomitant use of antihypertensive drugs may be necessary. Careful monitoring is essential. Digoxin should be discontinued as soon as possible.

Patients with severe carditis, such as carditis associated with rheumatic fever or viral myocarditis, are especially sensitive to digoxin-induced disturbances of rhythm.

Newborn infants display considerable variability in their tolerance to digoxin. Premature and immature infants are particularly sensitive, and dosage must not only be reduced but must be individualized according to their degree of maturity. Note: Digitalis glycosides are an important cause of accidental poisoning in children.

**PRECAUTIONS**
**General:** Digoxin toxicity develops more frequently and lasts longer in patients with renal impairment because of the decreased excretion of digoxin. Therefore, dosage requirements will be decreased in patients with moderate to severe renal disease (see DOSAGE AND ADMINISTRATION section in complete prescribing information). More time is required to achieve an initial or new steady-state concentration in patients with renal impairment than in patients with normal renal function.

In patients with hypokalemia, toxicity may occur despite serum digoxin concentrations within the "normal range," because potassium depletion sensitizes the myocardium to digoxin. Hypokalemia may result from diuretic, amphotericin B, or corticosteroid therapy, and from dialysis or mechanical suction of gastrointestinal secretions. It may also accompany malnutrition, diarrhea, prolonged vomiting, old age, and long-standing heart failure. In general, rapid changes in serum potassium or other electrolytes should be avoided, and intravenous treatment with potassium should be reserved for special circumstances as described below (see *Treatment of arrhythmias produced by overdosage*, in OVERDOSAGE section).

Calcium, particularly when administered rapidly by the intravenous route, may produce serious arrhythmias in digitalized patients. Hypocalcemia can nullify the effects of digoxin in man; digoxin may be ineffective until serum calcium is restored to normal.

Hypomagnesemia may predispose to digitalis toxicity. If low magnesium levels are detected in a patient on digoxin, replacement therapy should be instituted.

Quinidine causes a rise in serum digoxin concentration, with the implication that digitalis intoxication may result. This rise appears to be proportional to the quinidine dose. Because of the considerable variability of this interaction, digoxin dosage should be carefully individualized.

Patients with acute myocardial infarction or severe pulmonary disease may be unusually sensitive to digoxin-induced disturbances of rhythm.

Atrial arrhythmias associated with hypermetabolic states (eg, hyperthyroidism) are particularly resistant to digoxin treatment. Large doses of digoxin are not recommended as the only treatment of these arrhythmias and care must be taken to avoid toxicity. In hypothyroidism, the digoxin requirements are reduced. Digoxin responses in patients with compensated thyroid disease are normal.

Reduction of digoxin dosage may be desirable prior to electrical cardioversion to avoid induction of ventricular arrhythmias, but the physician must consider the consequences of rapid increase in ventricular response to atrial fibrillation if digoxin is withheld 1 to 2 days prior to cardioversion. If there is a suspicion that digitalis toxicity exists, elective cardioversion should be delayed. If it is not prudent to delay cardioversion, the energy level selected should be minimal at first and carefully increased in an attempt to avoid precipitating ventricular arrhythmias.

Incomplete AV block, especially in patients with Stokes-Adams attacks, may progress to advanced or complete heart block if digoxin is given.

In some patients with sinus node disease (i.e., sick sinus syndrome), digoxin may worsen sinus bradycardia or sinoatrial block.

In patients with Wolff-Parkinson-White syndrome and atrial fibrillation, digoxin can enhance transmission of impulses through the accessory pathway. This effect may result in extremely rapid ventricular rates and even ventricular fibrillation.

Digoxin may worsen the outflow obstruction in patients with idiopathic hypertrophic subaortic stenosis (IHSS). Unless cardiac failure is severe, it is doubtful whether digoxin should be employed.

Patients with chronic constrictive pericarditis may fail to respond to digoxin. In addition, slowing of the heart rate by digoxin in some patients may further decrease cardiac output.

Patients with heart failure from amyloid heart disease or constrictive cardiomyopathies respond poorly to treatment with digoxin.

Digoxin is not indicated for the treatment of sinus tachycardia unless it is associated with heart failure.

Intramuscular injection of digoxin is extremely painful and offers no advantages unless other routes of administration are contraindicated.

**Drug Interactions:** Potassium-depleting *corticosteroids* and *diuretics* may be major contributing factors to digitalis toxicity. *Calcium*, particularly if administered rapidly by the intravenous route, may produce serious arrhythmias. *Quinidine* causes a rise in serum digoxin concentration, with the implication that digitalis intoxication may result. *Antacids, kaolin-pectin, sulfasalazine, neomycin,* and *cholestyramine* may interfere with intestinal digoxin absorption, resulting in unexpectedly low serum concentrations. *Thyroid* administration to a digitalized hypothyroid patient may increase the dose requirement of digoxin. Concomitant use of digoxin and *sympathomimetics* increases the risk of cardiac arrhythmias, because both enhance ectopic pacemaker activity. *Succinylcholine* may cause a sudden extrusion of potassium from muscle cells, and may thereby cause arrhythmias in digitalized patients. Although *propranolol* and digoxin may be useful in combination to control atrial fibrillation, their additive effects on AV node conduction can result in complete heart block.

**ADVERSE REACTIONS**
The frequency and severity of adverse reactions to digoxin depend on the dose and route of administration, as well as on the patient's underlying disease or concomitant therapies (see PRECAUTIONS section). The overall incidence of adverse reactions has been reported as 5% to 20%, with 15% to 20% being considered serious (1% to 4% of patients receiving digoxin). Cardiac toxicity accounts for about one-half, gastrointestinal disturbances for about one-fourth, and CNS and other toxicity for about one-fourth of these adverse reactions.

**Adults:**
*Cardiac*—Unifocal or multiform ventricular premature contractions, especially in bigeminal or trigeminal patterns, are the most common arrhythmias associated with digoxin toxicity in adults with heart disease. Ventricular tachycardia may result from digitalis toxicity. Atrioventricular (AV) dissociation, accelerated junctional (nodal) rhythm, and atrial tachycardia with block are also common arrhythmias caused by digoxin overdosage.

Excessive slowing of the pulse is a clinical sign of digoxin overdosage. AV block (Wenckebach) of increasing degree may proceed to complete heart block.

Note: The electrocardiogram is fundamental in determining the presence and nature of these cardiac disturbances.

*Gastrointestinal*—Anorexia, nausea, vomiting, and, less commonly, diarrhea are common early symptoms of overdosage. Uncontrolled heart failure may also produce such symptoms.

*CNS*—Visual disturbances (blurred or yellow vision), headache, weakness, apathy, and psychosis can occur.

*Other*—Gynecomastia is occasionally observed.

**Infants and Children:**
Toxicity differs from the adult in a number of respects. Anorexia, nausea, vomiting, diarrhea, and CNS disturbances may be present but are rare as initial symptoms in infants. Cardiac arrhythmias are more reliable signs of toxicity. Digoxin in children may produce any arrhythmia. The most commonly encountered are conduction disturbances or supraventricular tachyarrhythmias, such as atrial tachycardia with or without block, and junctional (nodal) tachycardia. Ventricular

arrhythmias are less common. Sinus bradycardia may also be a sign of impending digoxin intoxication, especially in infants, even in the absence of first-degree heart block. Any arrhythmia or alteration in cardiac conduction that develops in a child taking digoxin should initially be assumed to be a consequence of digoxin intoxication.

**OVERDOSAGE** Treatment of arrhythmias produced by overdosage

**Adults:**

Digoxin should be discontinued until all signs of toxicity are gone. Discontinuation may be all that is necessary if toxic manifestations are not severe.

Potassium salts are commonly used, particularly if hypokalemia is present. Potassium chloride in divided oral doses totaling 3 to 6 grams of the salt (40 to 80 mEq K+) for adults may be given provided renal function is adequate (see below for potassium recommendations in infants and children).

When correction of the arrhythmia is urgent and the serum potassium concentration is low or normal, potassium should be administered intravenously in 5% dextrose injection. For adults, a total of 40 to 80 mEq (diluted to a concentration of 40 mEq per 500 ml) may be given at a rate not exceeding 20 mEq per hour, or slower if limited by pain due to local irritation. Additional amounts may be given if the arrhythmia is uncontrolled and potassium well tolerated. ECG monitoring should be performed to watch for any evidence of potassium toxicity (e.g., peaking of T waves) and to observe the effect on the arrhythmia. The infusion may be stopped when the desired effect is achieved.

Note: Potassium should not be used and may be dangerous in heart block due to digoxin unless primarily related to supraventricular tachycardia.

Other agents that have been used for the treatment of digoxin intoxication include lidocaine, procainamide, propranolol, and phenytoin, although use of the latter must be considered experimental. In advanced heart block, temporary ventricular pacing may be beneficial.

**Infants and Children:**

See Adults section (immediately above) for general recommendations for the treatment of arrhythmias produced by overdosage and for cautions regarding the use of potassium.

If a potassium preparation is used to treat toxicity, it may be given orally in divided doses totaling 1 to 1.5 mEq K+ per kilogram (kg) body weight (1 gram of potassium chloride contains 13.4 mEq K+).

When correction of the arrhythmia with potassium is urgent, approximately 0.5 mEq/kg of potassium per hour may be given intravenously, with careful ECG monitoring. The intravenous solution of potassium should be dilute enough to avoid local irritation; however, especially in infants, care must be taken to avoid intravenous fluid overload.

**DOSAGE AND ADMINISTRATION**

*Recommended dosages are average values that may require considerable modification because of individual sensitivity or associated conditions.* Diminished renal function is the most important factor requiring modification of recommended doses.

Due to the more complete absorption of digoxin from soft capsules, recommended oral doses are only 80% of those for tablets, elixir, and IM injection.

Because the significance of the higher peak serum concentrations associated with once-daily capsules is not established, divided daily dosing is presently recommended for:

1. infants and children under 10 years of age;
2. patients requiring a daily dose of 300 μg (0.3 mg) or greater;
3. patients with a previous history of digitalis toxicity;
4. patients considered likely to become toxic;
5. patients in whom compliance is not a problem.

Where compliance is considered a problem, once-daily dosing may be appropriate.

**Adults:**

*Adults: rapid digitalization with a loading dose*—Peak body digoxin stores of 8 to 12 μg/kg should provide therapeutic effect with minimum risk of toxicity in most patients with heart failure and normal sinus rhythm. Larger stores (10 to 15 μg/kg) are often required for adequate control of ventricular rate in patients with atrial flutter or fibrillation. Because of altered digoxin distribution and elimination, projected peak body stores for patients with renal insufficiency should be conservative (i.e., 6 to 10 μg/kg [see PRECAUTIONS section]).

The loading dose should be based on the projected peak body stores and administered in several portions, with roughly half the total given as the first dose. Additional fractions of this planned total dose may be given at 6- to 8-hour intervals, *with careful assessment of clinical response before each additional dose.*

If the patient's clinical response necessitates a change from the calculated dose of digoxin, then calculation of the maintenance dose should be based upon the amount actually given.

**Dosage for Previously Undigitalized Patients:**

In previously undigitalized patients, a single initial Lanoxicaps dose of 400 to 600 μg (0.4 to 0.6 mg) usually produces a detectable effect in 0.5 to 2 hours that becomes maximal in 2 to 6 hours. Additional doses of 100 to 300 μg (0.1 to 0.3 mg) may be given cautiously at 6- to 8-hour intervals until clinical evidence of an adequate effect is noted. The usual amount of Lanoxicaps that a 70-kg patient requires to achieve 8 to 15 μg/kg peak body stores is 600 to 1000 μg (0.6 to 1.0 mg).

*Adults: gradual digitalization with a maintenance dose*—The following table provides average Lanoxicaps daily maintenance dose requirements for patients with heart failure based upon lean body weight and renal function:

Usual Lanoxicaps Daily Maintenance Dose Requirements (μg) for Estimated Peak Body Stores of 10 μg/kg

| Corrected Ccr (ml/min per 70 kg) | Lean body weight (kg/lbs) 50/110 | 60/132 | 70/154 | 80/176 | 90/198 | 100/220 | Number of days before steady-state achieved |
|---|---|---|---|---|---|---|---|
| 0 | 50 | 100 | 100 | 100 | 150 | 150 | 22 |
| 10 | 100 | 100 | 100 | 150 | 150 | 150 | 19 |
| 20 | 100 | 100 | 150 | 150 | 150 | 200 | 16 |
| 30 | 100 | 150 | 150 | 150 | 200 | 200 | 14 |
| 40 | 100 | 150 | 150 | 200 | 200 | 250 | 13 |
| 50 | 150 | 150 | 200 | 200 | 250 | 250 | 12 |
| 60 | 150 | 150 | 200 | 200 | 250 | 300 | 11 |
| 70 | 150 | 200 | 200 | 250 | 250 | 300 | 10 |
| 80 | 150 | 200 | 200 | 250 | 300 | 300 | 9 |
| 90 | 150 | 200 | 250 | 250 | 300 | 350 | 8 |
| 100 | 200 | 200 | 250 | 300 | 300 | 350 | 7 |

*Example*—Based on the above table, a patient in heart failure with an estimated lean body weight of 70 kg and a Ccr of 60 ml/min should be given 200 μg (0.2 mg) of Lanoxicaps per day, usually taken as a 100 μg (0.1 mg) capsule after the morning and evening meals. Steady-state serum concentrations should not be anticipated before 11 days.

**Digitalizing Dose for Children:**

Usual Digitalizing and Maintenance Dosages for Lanoxicaps in Children With Normal *Renal Function Based on Lean Body Weight*

| Age | Digitalizing* Dose (μg/kg) | *Daily*† Maintenance Dose (μg/kg) |
|---|---|---|
| 2-5 Years<br>5-10 Years<br>Over 10 Years | 25-35<br>15-30 | 25%-35% of the oral or IV loading dose‡ |

*IV digitalizing doses are the same as Lanoxicaps digitalizing doses.
†Divided daily dosing is recommended for children under 10 years of age.
‡Projected or actual digitalizing dose providing desired clinical response.

More gradual digitalization can also be accomplished by beginning an appropriate maintenance dose. The range of percentages provided above can be used in calculating this dose for patients with normal renal function. In children with renal disease, digoxin dosing must be carefully titrated based upon desired clinical response.

Long-term use of digoxin is indicated in many children who have been digitalized for acute heart failure, unless the cause is transient. Children with severe congenital heart disease, even after surgery, may require digoxin for prolonged periods.

*It cannot be overemphasized that both the adult and pediatric dosage guidelines provided are based upon average patient response and substantial individual variation can be expected. Accordingly, ultimate dosage selection must be based upon clinical assessment of the patient.*

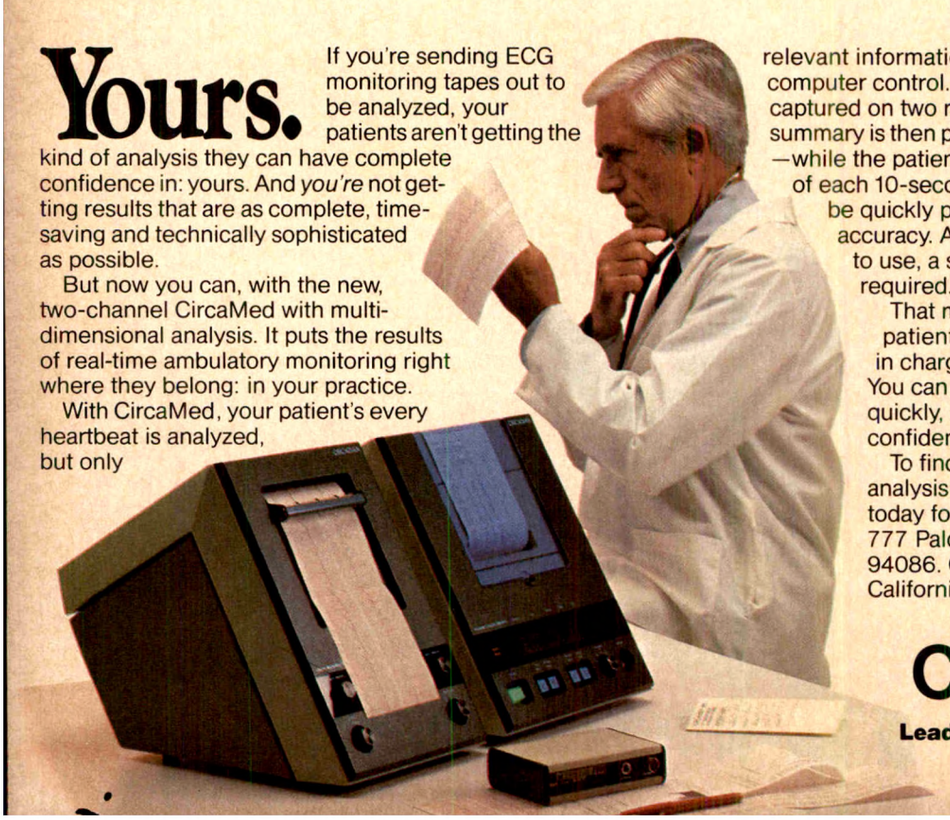
# Your patients deserve the best ECG analysis they can get.



**Yours.** If you're sending ECG monitoring tapes out to be analyzed, your patients aren't getting the kind of analysis they can have complete confidence in: yours. And *you're* not getting results that are as complete, time-saving and technically sophisticated as possible.

But now you can, with the new, two-channel CircaMed with multi-dimensional analysis. It puts the results of real-time ambulatory monitoring right where they belong: in your practice.

With CircaMed, your patient's every heartbeat is analyzed, but only relevant information is recorded, under micro-computer control. Up to two days of patient data are captured on two multi-dimensional channels; a summary is then printed in your office within minutes —while the patient is still there. A strip chart record of each 10-second ECG measurement can also be quickly produced for further diagnostic accuracy. And because CircaMed is simple to use, a specially trained technician isn't required.

That means now neither you nor your patients have to worry about who's in charge of their ECG analysis: you are. You can both count on getting results quickly, economically and with complete confidence.

To find out how easy it is to bring ECG analysis into your practice, write us today for a brochure or demonstration: 777 Palomar Avenue, Sunnyvale, CA 94086. Or call: (800) 538-1772. In California (408) 738-8550.

**Leaders in real-time ECG analysis.**

# Can Tracking of Contrast Echocardiographic Targets Be Used to Measure Intracardiac Flow Velocities?

LILLIAM M. VALDES-CRUZ, MD, DAVID J. SAHN, MD, SUZANA HOROWITZ, BS, DANIEL C. FISHER, MD, STANLEY J. GOLDBERG, MD, and HUGH D. ALLEN, MD

**Recent studies suggest that the slopes of linearly moving echocardiographic contrast targets (microbubbles) can be used to predict flow velocities in the right heart. The purpose of this study was to assess the accuracy of velocities measured with contrast echocardiography by comparing them with those recorded with a previously calibrated quantitative range-gated 2-dimensional echocardiographic Doppler flow meter. Venous saline echocardiographic contrast injections and Doppler studies were performed in 10 patients, aged 6 months to 16 years, who had been operated on for lesions in the left side of the heart. Blood velocities were measured on a Doppler flow meter along the direction of flow in the main pulmonary artery just distal to the pulmonary valve in a short-axis plane. Immediately after the Doppler study, an M-mode echocardiogram of the pulmonary valve was derived from the same plane as that used for the preceding Doppler sample volume, passing through the pulmonary valve; 2 to 10 ml of normal saline solution was forcefully hand-injected through a previously positioned peripheral venous line and recorded on strip chart and videotape at a paper speed of 100 mm/s. Pulmonary flow velocities by contrast echocardiography were measured as the slopes of the moving contrast echocardiographic targets seen just beyond the pulmonary valve leaflets. Measurable microbubbles had to follow the constraints described in a previous study by Shiina et al.[3] Doppler velocities were read directly from the machine calibration marks (centimeters per second) recorded with the fast Fourier output. Instantaneous and peak velocities were determined at time-matched systolic points in cardiac cycles of identical R-R intervals. Significant but low level correlations were found between contrast echocardiography and Doppler instantaneous ($r = +0.45$) or peak ($r = +0.11$) systolic velocities. Our results suggest that while contrast echocardiographic microbubbles can be measured to yield a velocity, they do not behave like moving red blood cells that reflect ultrasound to produce a Doppler shift. Therefore, contrast echocardiography cannot be used reliably to measure flow velocities in the right heart.**

Recently, there has been interest in analyzing echocardiographic contrast targets (microbubbles) as qualitative indicators of blood flow patterns in the right heart, specifically for identifying tricuspid or pulmonary insufficiency, or both.[1,2] Attempts at quantitation suggest that the slopes of linearly moving contrast echocardiographic microbubbles imaged within the tricuspid and pulmonary valve orifices afford reasonably accurate estimates of instantaneous blood flow velocity at those sites.[3] These results imply that microbubbles behave physiologically like moving red cells within the bloodstream. The present study was designed to test this hypothesis and to assess the accuracy of contrast echocardiographic velocities by comparing them with simultaneously measured instantaneous and peak velocities recorded with a quantitative 2-dimensional range-gated echocardiographic Doppler flow meter (Electronics for Medicine/Honeywell). The Doppler flow meter measurements had previously been calibrated against an electromagnetic flow meter in open-chest dogs and against indicator dilution and oximetry in children during cardiac catheterization.[4,5]

From the Department of Pediatrics, University of Arizona, Health Sciences Center, Tucson, Arizona. Manuscript received March 16, 1982; revised manuscript received June 28, 1982, accepted July 1, 1982.

## Methods

The study population consisted of 10 postoperative patients, aged 6 months to 16 years, with lesions in the left side of the heart (coarctation of the aorta in 5, patent ductus arteriosus ligation in 3, and aortic stenosis in 2). All underwent clinically indicated echocardiographic contrast studies and all had a stable central hematocrit of 30 to 38% measured within 12 hours of the study.

Bedside Doppler studies were performed with the patient in the supine position using a prototype Electronics for Medicine/Honeywell range-gated pulsed Doppler unit. This unit contains a 3.5 MHz single element transducer, mechanically swept through a 60° arc to achieve a real-time 2-dimensional echocardiographic image that can be stopped along any image line. A variable-sized Doppler sample volume can then be positioned at any depth on that line, allowing appreciation of its location and angulation relative to flow (Fig. 1). The operational mode of the unit can then be switched from real-time to range-gated pulsed Doppler in less than 1/10 second. Two outputs are available in Doppler mode, the first an audio signal, and the second a fast Fourier transform spectral analysis sampled at 200 times/s. The Doppler output and simultaneous echocardiographic trace can be recorded on a strip chart or video tape, or both (Fig. 1). The fast Fourier output can be converted to velocity of flow in centimeters per second based on the formula: Velocity of flow = frequency shift × velocity of sound in the medium/2 × transmitted frequency × cos $\theta$, where cosine $\theta$ equals the angle between the Doppler beam and the direction of flow.

Ultrasonic studies began with 2-dimensional imaging of the right ventricular outflow tract, pulmonary valve, main pulmonary artery, and its bifurcation from a standard parasternal short-axis plane. The Doppler sample volume was then positioned along the direction of flow in the pulmonary valve orifice immediately distal to the plane of the closed pulmonary valve. It was adjusted so that no pulmonary valve echoes crossed through it (Fig. 1). Once the optimal 2-dimensional image and Doppler output were obtained and the sample volume was confirmed to be as parallel as possible to the apparent direction of flow (cos 0° = 1), the 2-dimensional image was recorded on a strip chart to verify Doppler position followed by recording of the fast Fourier outputs of the Doppler flow velocity curves on strip chart and videotape.

Immediately after the Doppler study, and with the patient still in the supine position, an M-mode echocardiogram of the pulmonary valve was derived from the 2-dimensional short-axis view along the same line as that used to position the preceding Doppler sample volume, passing through the pulmonary valve. While continuously recording this M-mode on a strip chart and videotape, 2 to 10 ml of normal saline solution was forcefully hand-injected through a previously positioned peripheral venous line.

A lead II electrocardiogram was recorded throughout the entire study for timing purposes. All recordings were made at a paper speed of 100 mm/s.

**Analysis of records:** Beats selected for measurement of echocardiographic contrast slopes and Doppler flow curves occurred at peak inspiration and were R-R matched from the preceding to the following cardiac cycle.

Instantaneous echocardiographic contrast flow velocities were determined by measuring the slopes of 2 to 6 contrast targets for each patient with a computerized clinical graphics analyzer (Numonics®) calibrated for distance (centimeters) and time (milliseconds) before each measurement. The time of each microbubble slope was measured relative to the pulmonary valve opening. Following the methods described by Shiina et al,[3] measurable microbubbles had the following constraints: They had to be straight, had to measure at least 1.5 cm in length, and had to occur within 120 ms after pulmonary valve opening, the most rapid phase of right ventricular ejection. With the onset of systolic flow as indicative of pulmonary valve opening, points in the corresponding Doppler flow velocity curve were time-matched to those of the previously measured microbubbles. Instantaneous Doppler velocities were read directly from the machine calibration marks (centimeters per second) recorded with the fast Fourier outputs (Fig. 1).

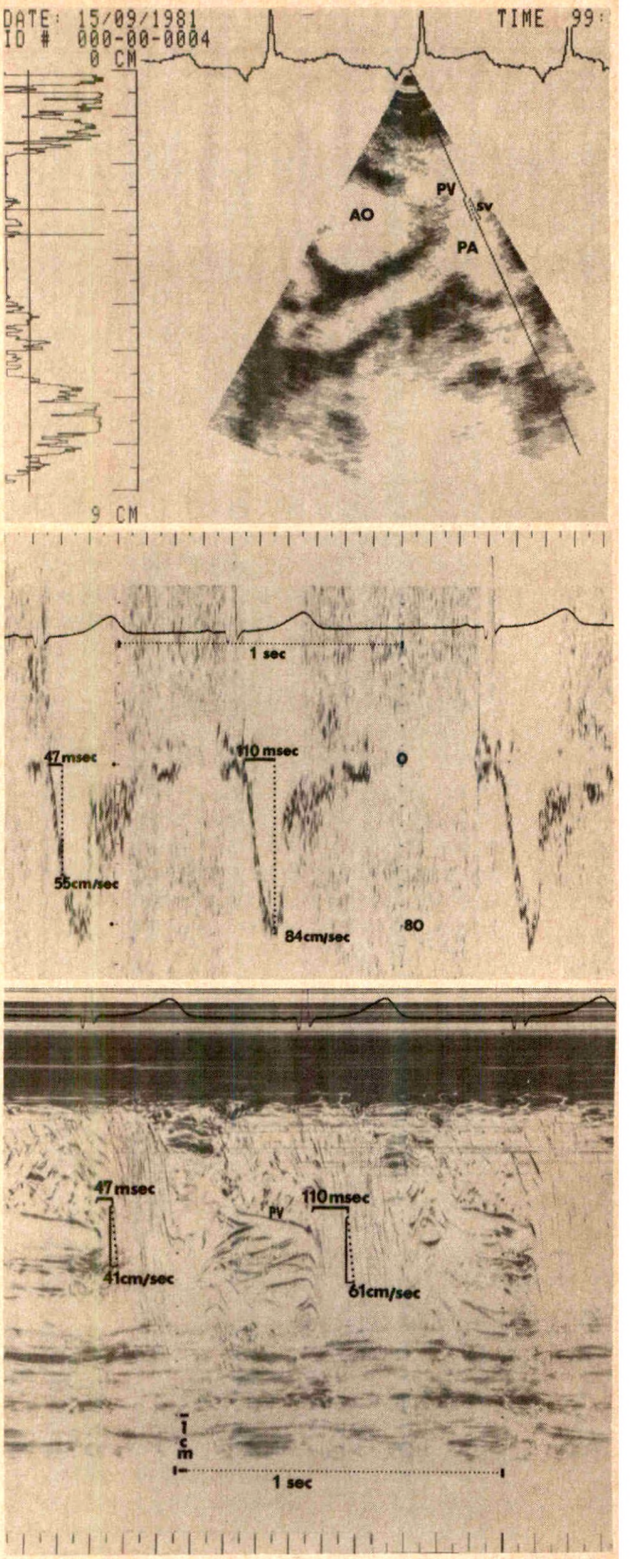

**FIGURE 1. Top,** parasternal short-axis view of the pulmonary valve, main pulmonary artery, and branches with Doppler sample volume positioned along the line of flow within the main pulmonary artery distal to the pulmonary valve. **Middle,** Doppler output derived from that sampling site. Instantaneous and peak velocities, read directly from calibration marks (cm/s), are indicated at 47 and 110 ms, respectively. **Bottom,** the saline contrast injection recorded at the pulmonary valve. The slopes of the linearly moving microbubbles, selected at time-matched points, are indicated in the figure. See text for details.

Peak Doppler velocity was read directly from the recorded calibration marks, and its time from the onset of systolic flow determined in milliseconds. For each patient, microbubbles occurring at the same systolic time were then selected from the corresponding M-mode trace and their slope was measured using the aforementioned graphics analyzer (Fig. 1).

**Repeatability of measurements:** To determine repeatability, each slope and Dopper velocity were measured in duplicate. To test interobserver variability, slopes and Doppler curves were measured by a second investigator who was unaware of previous results or patient identity.

**Statistical analysis:** Correlation coefficients were used to compare velocity results obtained by Doppler with those obtained by echocardiographic contrast. The paired $t$ test was used to analyze measurement repeatability and interobserver variability.

## Results

Contrast and Doppler studies were satisfactory in all 10 patients. Instantaneous velocities were measured from 2 to 6 contrast echocardiographic targets in each patient and matched to their corresponding systolic points in the Doppler flow curve, which resulted in 38 matched instantaneous velocities. In addition, peak Doppler velocities were compared with echocardiographic contrast slopes in all 10 patients, resulting in 10 individual peak velocity points.

**Correlation of Doppler with echocardiographic contrast velocities (Fig. 2):** Significant but low level correlations were found between time-matched echocardiographic contrast and Doppler instantaneous (r = +0.45) or peak (r = +0.11) systolic velocities.

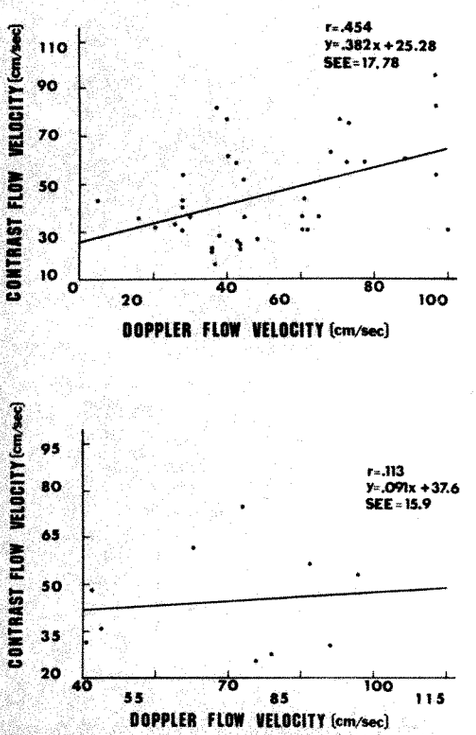

**FIGURE 2.** Regression lines comparing the instantaneous (**top**) and peak (**bottom**) velocities measured by echocardiographic contrast slopes and by the Doppler flow meter. Only low level correlations were found for each of the 2 regression lines.

**Interobserver variability and errors of repeatability:** The echocardiographic contrast slope and Doppler velocity measurements were highly repeatable. The standard error of the mean testing repeatability was <5% when comparing duplicate measurements on a given record. Furthermore, interobserver variability in measuring the slopes or Doppler velocities was also <5%.

## Discussion

Our results indicate that the slope of the trajectory of linear echocardiographic contrast targets correlates poorly with the flow velocity of red blood cells measured by a range-gated 2-dimensional echocardiographic Doppler flow meter.

Use of Doppler methods to measure flow velocity has been plagued with technical problems, mostly related to the inability to assess the intercept angle at which flow is being sampled and to difficulties in linearly measuring Doppler frequency shifts.[3,6–14] Doppler measurement of flow velocity is a function of the cosine of the intercept angle; consequently, flow determination is maximized when the Doppler beam is oriented exactly parallel (at 0° angle) to the direction of flow. Peak velocity is significantly reduced when the sound beam is deviated from 0°. Units combining Doppler with M-mode echocardiography allow estimation of the position of the sample volume; however, the critical intercept angle cannot be determined. The prototype system used in this study permits control and approximation of such an angle in 2 planes. The angle in the third plane (elevational) cannot be measured. However, minimal deviations from an intercept angle of 0° are of no practical importance, because the cosine of the small deviant angle is still quite close to unity.

Accuracy of the Doppler flow meter used in our study was verified in our animal and clinical laboratories.[4,5] Doppler measurements of blood flow velocity (and derived stroke volume and cardiac output) in the ascending aorta of open chest dogs compared favorably with simultaneous determinations made with an electromagnetic flow meter (r = +0.95, standard error of the estimate [SEE] = 0.035).[4] More recently, Doppler flow velocities measured in the ascending aorta and pulmonary artery of children during cardiac catheterization and used to calculate systemic and pulmonary blood flows and QP:QS correlated well with simultaneous determinations made with standard indicator dilution or oximetric techniques (r = 0.86, SEE = 0.83).[5] These 2 separate studies indicate that velocity measurements obtained with the 2-dimensional range-gated Doppler flow meter and used as the reference standard in this study are accurate estimates of flow velocity in both the experimental and the clinical setting.

We did not take advantage of the capability of our instrumentation to record echocardiographic contrast targets simultaneously with Doppler (that is, the potential for a QM or flow M-mode tracing), because in our experience the velocities detected by Doppler while contrast is injected are the velocities of microbubbles and not those of red cells. The reason is that microbubbles present an overwhelmingly stronger signal than do the red cells; consequently, simultaneous sampling

would not allow determination of whether microbubble velocities reflect those of red cells. As stated in the Methods section, the Doppler sample volume was placed directly within the pulmonary valve orifice just distal to the closed position of the leaflets and just far enough so that no pulmonary valve echoes crossed through it. The slopes were measured in systole after the valve had opened and at a position along the M-mode line which was posterior or distal to the closed position of the valve (Fig. 1). Therefore, the position at which the microbubble slopes were measured within the pulmonary valve orifice corresponds quite closely to the position of the Doppler sample volume, that is, both were <1 cm distal to the level of the closed pulmonary valve.

In this investigation, we elected to measure echocardiographic contrast and Doppler velocities exclusively in the main pulmonary artery just distal to the pulmonary valve to minimize errors due to irregular blood flow patterns elsewhere. In addition, following the recommendations of Shiina et al,[3] we only considered echocardiographic contrast targets measuring >1.5 cm in length to assure that the selected target was moving approximately parallel to the ultrasound beam and therefore represented close to maximal echocardiographic contrast velocity.[3] Furthermore, because theoretically the vector velocity of the microbubbles could be the result of a complex relation between blood flow and gravity, all patients were studied supine to avoid changes in gravity factor with different patient positions. Finally, all patients selected for inclusion in the study had a similar hematocrit level and had lesions in the left side of the heart with no clinical or Doppler evidence of turbulent pulmonary flow, or both. Because motion of microbubbles could be affected by the density of the medium, that is, the blood, which in turn may vary in conditions of turbulent versus laminar flow, imposing these added constraints was an attempt to minimize these potential sources of error. Despite these precautions and acceptable errors in repeatability and interobserver variability, only low level correlations were found between Doppler and echocardiographic contrast instantaneous and peak velocities.

We conclude that contrast echocardiographic targets (microbubbles) do not behave physiologically like the moving red blood cells that produce the Doppler shift. Although the slopes of their trajectories can be measured to yield a velocity, these do not match the velocity of red cells within the blood stream as measured with a range-gated 2-dimensional echocardiographic Doppler system. Therefore, contrast echocardiography cannot be used to reliably measure flow velocity in the right heart.

# Cardiac Localization of Transvascular Bioptome Using 2-Dimensional Echocardiography

JAMES W. FRENCH, MD, RICHARD L. POPP, MD, and PAUL T. PITLICK, MD

**Two-dimensional (2-D) echocardiography was added to standard fluoroscopic localization of transvascular endomyocardial biopsy in 7 children with heart muscle disease whose ages were 6 months to 18 years. One left ventricular and 11 right ventricular biopsies were carried out without complications using the fluoroscopic-echocardiographic technique. Two-dimensional echocardiographic monitoring has the advantages of reducing radiation exposure and providing anatomic information about intracardiac structures as well as bioptome localization. Lateral beam spread and reverberation artifacts represent potential problems with 2-D echocardiography, but they did not cause significant difficulties in this study.**

Transvascular endomyocardial biopsy was described by Sakakibara and Konno[1] in 1962. Although application of the procedure remains limited,[2] the technique is used in several medical centers to diagnose and monitor various forms of heart muscle disease.[3–12] A special bioptome is passed into a peripheral vessel and guided into a ventricular chamber using fluoroscopic control. Access to the right heart is usually obtained by percutaneous introduction of the bioptome into the right internal jugular vein.[3,4] Femoral approaches to both the right and left ventricle also have been described.[5–7] This report evaluates the addition of 2-D echocardiography to the biopsy procedure to facilitate positioning of the bioptome in the heart.

## Methods

Patients with a clinical diagnosis of cardiomyopathy were selected for biopsy to make a specific diagnosis of myocarditis, to confirm the clinical impression of heart muscle disease, or to monitor drug effects on the myocardium (Table I). The patient, parents, or both were fully informed and consent was obtained. Patients were prepared for the biopsy as previously reported for the jugular (right heart) or femoral (left heart) approach.[3–7] Either heavy sedation with a combination of meperidine and diazepam or light general anesthesia was employed, depending upon patient anxiety. The biopsy procedure was usually combined with standard right or left heart catheterization.

Two-dimensional echocardiography using commercially available instruments and 2.25, 3.5, or 5 MHz transducers was used to position the bioptome. The 2.25 and 3.5 MHz transducers were wide angle (80°) phased array units (Hewlett-Packard). In 2 cases (Patients 5 and 7) a 5 MHz 30° oscillating head (Smith Kline Instruments) was employed. The higher frequency instrument improved the picture quality, but the oscillating motion created a significant problem during attempts to maintain a stable chest position. In all patients sector scanning was initiated from a subcostal or apical window and the transducer was orientated for an optimal 4-chamber or long-axis view which allowed imaging of the septal and, with transducer angulation, the inferior surface of the ventricular chamber. Each patient required some variation in transducer placement. Because the patient was positioned on the fluoroscopy table to optimize catheter introduction and was relatively fixed, we tested several transducer positions before introduction of the bioptome. In the left heart study, alternating between an apical long axis and a left ventricular

**TABLE I Clinical Synopsis of Patients**

| Patient | Age | Biopsy | Clinical Diagnosis |
|---|---|---|---|
| 1 | 13 yr | RV | Myopathy (C, restrictive; S) |
| 2 | 11 yr | RV | Histiocytosis |
| 3 | 16 yr | RV | VT, VF, rule out CM |
| 4 | 7 yr | RV (2)* | Kearns-Sayre syndrome |
| 5 | 6 mo | RV | Myocarditis |
| 6 | 18 yr | RV (4)* | Myocarditis |
| 7 | 9 mo | RV, LV | Myocarditis |

* Number of procedures. C = cardiac muscle; CM = cardiomyopathy; LV = left ventricular biopsy; RV = right ventricular biopsy; S = skeletal muscle; VF = ventricular fibrillation; VT = ventricular tachycardia.

short axis provided the best visualization of the bioptome position relative to the septal surface and the posteromedial papillary muscle. Although it was possible to image a large part of the bioptome shaft as it passed through the right atrium or the aorta, during the biopsy procedure the view which provided an optimal image of the bioptome head contacting the myocardium was utilized (Fig. 1). During a single biopsy procedure, 3 to 5 tissue samples were obtained for analysis.

Initially, the ultrasound transducer was positioned so that it was out of the fluoroscopic field. The echocardiographer wore a lead glove in addition to the usual protective vest and 2-D echocardiography was used simultaneously with fluoroscopsy. When used in this manner the lead glove and the fluoroscopy unit made it difficult to properly position the ultrasonic transducer and impossible to maintain a position for more than a few minutes. In the last 6 procedures, as we gained confidence in ultrasonic localization, we alternated fluoroscopic and echocardiographic imaging: fluoroscopic monitoring was used to place the bioptome across the tricuspid or aortic valve, and 2-D echocardiography was then used for ventricular positioning. Each patient was checked for pneumothorax by fluoroscopy and for pericardial effusion by echocardiography at the completion of the procedure.

## Results

Two-D echocardiography was used to monitor 1 left ventricular and 11 right ventricular biopsy procedures in 7 patients. Patient 6 had 4 serial biopsy procedures to monitor the effect of steroids and immunosuppression on his myocarditis. In Patient 4 there were diagnostic problems, and myocarditis was initially thought to be the cause of acquired complete heart block. The first biopsy was equivocal, while the second suggested noninflammatory cardiomyopathy. The remaining patients had single biopsy procedures, although Patient 7 had both left and right ventricular biopsies. All right ventricular biopsies were accomplished with a percutaneous internal jugular approach, while the left ventricular study was done through the femoral artery. In each case the bioptome and its relation to valve leaflets, chordae, papillary muscles, and the myocardium were readily visualized by echocardiography (Fig. 1 and 2). Frequently, initial positioning directed the bioptome into the ventricular free wall, or toward the atrioventricular valve apparatus (Fig. 2). In more than 50% of our cases some repositioning of the catheter was necessary before the tissue sample was obtained. This usually involved backing and rotating the catheter in the ventricle, and was easily accomplished using 2-D echocardiography (Fig. 2). In this series of patients the myocardial abnormality was considered homogeneous, and no particular attempt was made to direct the catheter to a "new" myocardial position for each tissue sample. No complications were identified using the combined technique. The biopsy procedure was not significantly prolonged as a result of the echocardiographic monitoring.

## Discussion

Since its introduction, transvascular endomyocardial biopsy has provided valuable data on several of the heart muscle disease groups. The most important at Stanford, in terms of patient numbers, have been staging of anthracycline-induced cardiomyopathy,[8] the histologic diagnosis of myocarditis,[9] and detection of rejection in patients who have undergone heart transplantation[3] or heart and lung transplantation.[10] The

technique is also useful in patients with the suspected diagnoses of infiltrative or storage abnormalities of the myocardium such as amyloidosis, sarcoidosis, or hemochromatosis.[11,12] Patients in the current study group had biopsies for a more precise histologic diagnosis when the differential diagnosis included cardiomyopathy or myocarditis, or both; to monitor immunosuppressive therapy for inflammatory myocardial disease; or to rule out myocardial infiltrative disease (histiocytosis) in a patient who had previously received doxorubicin.

The standard approach to right ventricular biopsy in our institution is to introduce the bioptome percutaneously into the right internal jugular vein and advance the biopsy catheter into the right ventricle under fluoroscopic control. The appearance of premature ventricular contractions on the electrocardiogram and "resistance" to catheter advancement identify contact with the ventricular wall. Although cardiac perforation, pneumothorax, embolism, arrhythmias, and nerve palsies have been reported,[4] meticulous attention to technique has resulted in a very low incidence of complications. The procedure is well tolerated and can be performed on adult outpatients, although fluoroscopy is required. With continuing improvement in echocardiographic instrumentation and the demonstration that other types of intracardiac catheters could be imaged with ultrasound,[13–15] the addition of 2-D echocardiography to the biopsy protocol offered the potential for reducing radiation exposure and for providing an anatomically detailed intracardiac image to position the biopsy catheter. The introduction of 2-D echocardiography was not expected to reduce the already-low incidence of biopsy-related complications in the adult with dilated (congestive) cardiomyopathy. However, in young children or in other patients whose ventricles are small or abnormally shaped (as in hypertrophic or obliterative cardiomyopathy, endocardial fibroelastosis, or myocardial storage disease), the ability to visualize ventricular boundaries and intracardiac structures such as atrioventricular valve apparatus assumes greater importance. The right ventricle is biopsied more often, but the capacity to identify left ventricular structures is equally valuable. Even though the thicker left ventricular wall makes perforation less likely, the integrity of the valve structures is more critical.

This patient series demonstrates some important differences between fluoroscopy and 2-D echocardiography as imaging techniques. Fluoroscopy presents positional information about the overall cardiac silhouette. With the use of fluoroscopy the catheter is positioned near the apex of the cardiac shadow in the frontal plane. No additional anatomic information is available for bioptome localization. It is assumed that this position plus the catheter rotation used to manipulate the bioptome orients the catheter tip into the apical portion of the ventricular septum.[4] In patients without congenital anatomic abnormalities and with normal or large ventricular chambers this has been a very satisfactory technique. Multiple imaging planes, although available, usually are not used. Anatomic variations, as in the infants (Patients 5 and 7) with relatively small hearts and the child (Patient 1) with restrictive cardiomyopathy and small ventricular

chambers, are better evaluated with the anatomic information available from the echocardiographic image. Multiple variations in image planes were used in all patients to identify the catheter and important anatomic landmarks. Although fluoroscopy times were not examined systematically we now use 2-D echocardiography almost exclusively for ventricular positioning, thus avoiding that radiation exposure. A disadvantage to the combined use of 2-D echocardiography and fluoroscopy is the necessity of an additional physician or technician to operate the echocardiographic equipment.

An inherent problem in biopsy procedures of this type is the question of representative sampling.[2] Most heart

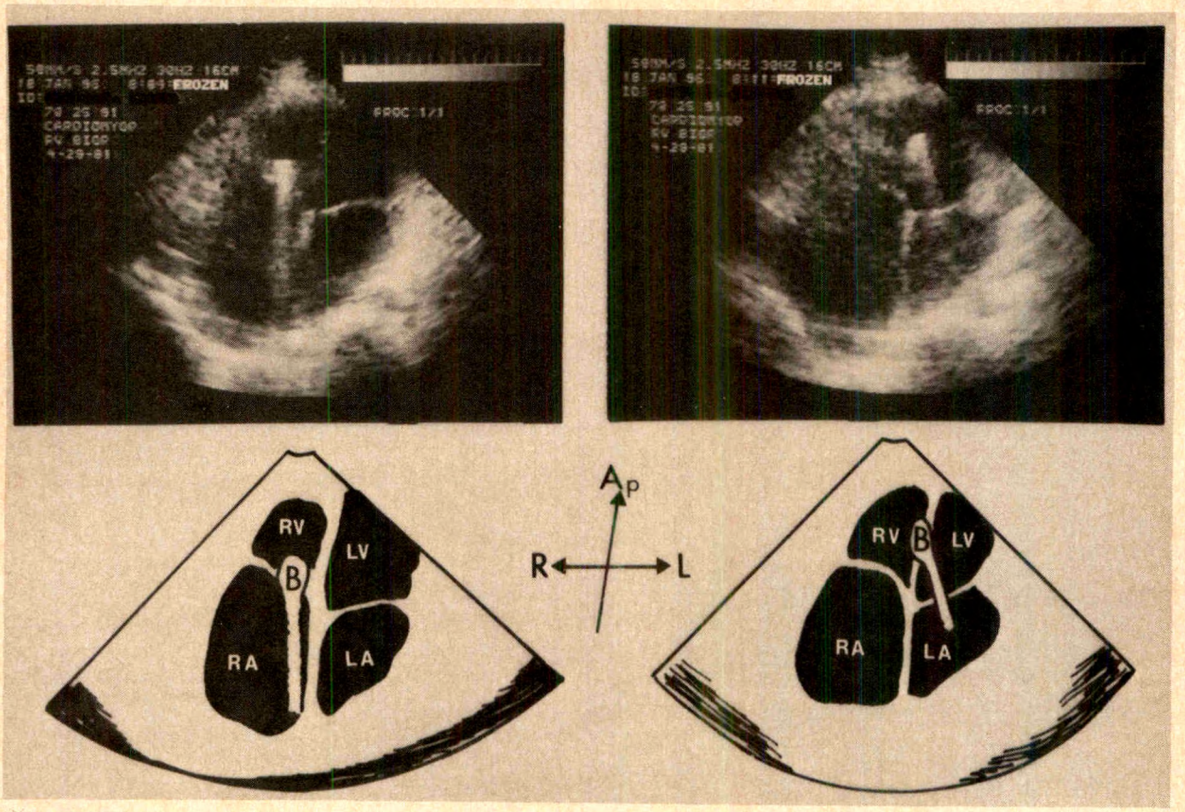

**FIGURE 3.** Reverberation artifacts. **Left panel,** 4-chamber view, bioptome positioned in the mid-right ventricle. There is a reverberation artifact which does not cross the atrial or ventricular septa. **Right panel,** 4-chamber view, same study, slight change in image plane and catheter position. Note that the artifact now makes the catheter appear to cross the mitral valve, enter the left ventricle, and cross the plane of the ventricular septum. Abbreviations as in Figures 1 and 2.

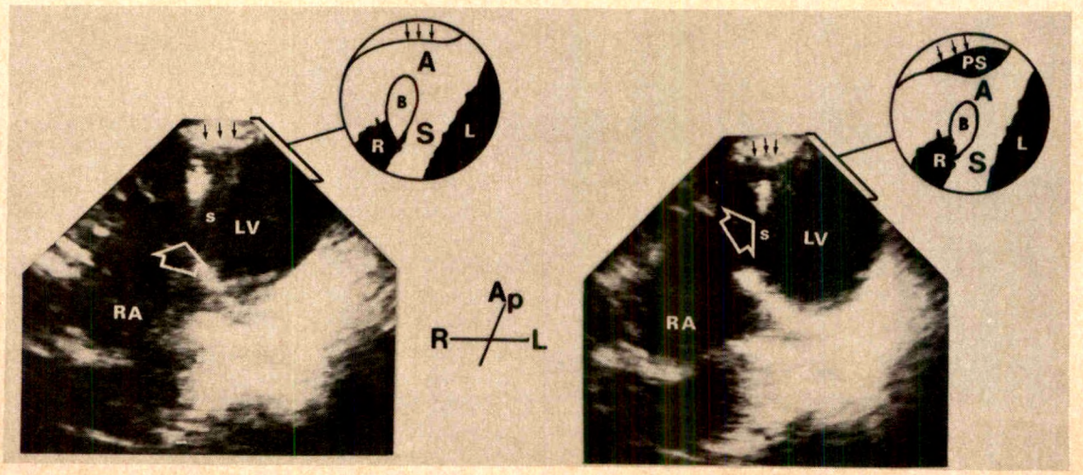

**FIGURE 4.** Monitoring the biopsy myomectomy. **Left panel,** 4-chamber view, with bioptome tip positioned to remove a specimen. **Right panel,** when the bioptome was withdrawn, the myocardium briefly separated from the pericardium (**small arrows**). Abbreviations as in Figure 1.

muscle disease has some degree of heterogeneity, and there is frequently concern whether the sampled site is an accurate reflection of the generalized myocardial disease process. This study demonstrates that 2-D echocardiography currently allows visual identification of the site before biopsy. The ease with which multiple echocardiographic imaging planes can be obtained should help assure multiple sampling sites and an accurate knowledge of the site of each sample. With the real possibility that ultrasonic tissue characterization of a designated area of myocardium may be available in the future,[16,17] 2-D echocardiography offers the potential for both gross identification and ultrasonic interrogation of the biopsy site before the tissue sample is taken. The enhanced ability to localize the bioptome with echocardiography may also allow applications in localized myocardial disease such as intramural tumors or myocardial disease in patients with cardiac malposition where fluoroscopic orientation is not adequate for biopsy localization.

Lateral beam spread and reverberation artifacts create potential limitations on the accuracy of catheter localization using 2-D echocardiography. Lateral beam spread was not a major problem in this study because we localized the catheter tip and tended to ignore other parts of the catheter; furthermore, variations of a few millimeters were not critical for structure identification during the biopsy procedures in our patients. However, when the ventricle or ventricles are very small, in infants for example, or where the value of the biopsy depends upon precise localization of the biopsy site, resolution requirements may exceed the capabilities of some echocardiographic instruments. Reverberation artifacts from the metal catheter were common (Fig. 3) but did not cause problems during this study. Because the tip of the catheter was closest to the transducer, artifact trailing posteriorly (away from the area of greatest interest) did not interfere with tip localization and usually did not obscure structures near the tip. At times the catheter seemed to cross the plane of the ventricular septum (Fig. 3), but this phenomenon could be identified as artifact by changing the echocardiographic imaging plane, moving the catheter slightly, or noting that the catheter tip remained within the proper ventricle.

Echocardiography also provides a dynamic picture of the biopsy procedure. For example, in Patient 1 the myocardium was fibrosed and initial attempts to retrieve the closed bioptome caused sufficient myocardial displacement that a significant pericardial "space" was created without separation of a biopsy sample (Fig. 4). The bioptome was opened, repositioned in the ventricular apex, and a satisfactory biopsy sample was obtained. The most sensitive indicator of "reasonable force," a term used to guide new practitioners, when separating the tissue sample from the myocardium is the experience of the bioptome operator. However, the capacity to observe the initial position of the bioptome and the degree of pericardial separation using 2-D echocardiography during the biopsy provide secondary information which is valuable when repositioning of the bioptome is necessary.

An interesting observation was the appearance of periodic waves of ultrasonic targets when the bioptome was moved or when a specimen was obtained. The phenomenon was not associated with any clinical adverse effects. The targets probably resulted from atmospheric gas adhering to the surface of the bioptome. The ultrasonic appearance is analogous to the previously described "ultrasonic contrast injections" using indocyanine green, saline solution, or the patient's blood.[18]

We conclude that the addition of 2-D echocardiography to the myocardial biopsy procedure allows enhanced visualization of the bioptome position, particularly with regard to intracardiac structures. This is most advantageous with small, unusually shaped, or abnormally positioned ventricles, or when a specific biopsy site is required. A combination of fluoroscopy and 2-D echocardiography used alternately provided the best visualization and allowed immediate monitoring for complications such as pneumothorax or pericardial effusion.

## Addendum

Since submission of this work, we performed right ventricular endomyocardial biopsies in 2 more children, aged 11 and 14 months, and whose weights were 7 and 8 kg, respectively. In both, echocardiographic localization of the bioptome was superior to fluoroscopy, and there were no complications.

# Validation of the Angiographic Accuracy of Digital Left Ventriculography

ALLEN B. NICHOLS, MD, ERIC C. MARTIN, MD, THOMAS P. FLES, BS, KAREN M. STUGENSKY, BA, LAWRENCE A. BALANCIO, RT, WILLIAM J. CASARELLA, MD, and MELVIN B. WEISS, MD

**Digital subtraction angiography enhances the contrast to background signal, enabling the performance of angiography with reduced doses of contrast medium. The objectives of the present study were (1) to validate the accuracy of digital left ventriculography for measurement of left ventricular volumes and segmental contraction; and (2) to compare the hemodynamic effects resulting from low- and high-dose intraventricular contrast injections. Twenty-eight patients underwent digital left ventriculography, performed by intraventricular injection of 7 ml of contrast medium diluted in saline solution, followed by conventional cineangiography of the left ventricle performed with 45 ml of undiluted contrast medium. Left ventricular volumes calculated from digital ventriculograms correlated well with volumes calculated from conventional ventriculograms: end-diastolic volume (r = 0.97, standard error of estimate [SEE] 23.4 ml; end-systolic volume (r = 0.97, SEE 15.4 ml); stroke volume (r = 0.95, SEE 14.7 ml); and ejection fraction (r = 0.97, SEE 3.8%). Segmental left ventricular contraction, measured as percent chordal shortening of hemiaxes, correlated moderately well (r = 0.81, SEE 11.5%). After injection of undiluted contrast medium, left ventricular systolic pressure decreased (133 ± 31 to 123.5 ± 27 mm Hg; p <0.01) and left ventricular end-diastolic pressure increased (12.0 ± 7 to 16.9 ± 10 mm Hg; p <0.001). Left ventricular systolic and end-diastolic pressures did not change significantly after injection of diluted contrast medium, and patients had no discomfort. Thus, digital subtraction angiography permits the performance of left ventriculography with markedly reduced doses of contrast medium, obviating the hemodynamic effects resulting from injection of conventional doses of contrast medium. This new approach to left ventriculography provides high resolution ventriculograms for accurate measurement of left ventricular volumes, stroke volume, and ejection fraction.**

The diagnostic potential of conventional left ventriculography is limited by the relatively large doses of contrast medium necessary to adequately opacify the left ventricular cavity. Conventional doses of contrast medium cause hemodynamic alterations[1,2] which have been attributed to the direct myocardial depressant effect of contrast medium,[3,4] to the effect of a sudden increase in left ventricular volume caused by power injection,[5] and to peripheral vasodilation and secondary reflex responses resulting from the hypertonicity of contrast medium.[6] In studies in animals, intraventricular injections of cortrast medium cause an acute increase in left ventricular volumes,[7,8] but the effect of contrast injections on ventricular volumes in patients is controversial. Finally, the nephrotoxicity resulting from high doses of contrast medium[9] precludes multiple contrast injections for ventriculographic assessment of the effect of therapeutic interventions on left ventricular performance.

From the Departments of Medicine and Radiology, College of Physicians and Surgeons, Columbia University, New York, New York. Manuscript received December 21,1981; revised manuscript received May 11, 1982, accepted July 1, 1982.

Address for reprints: Allen B. Nichols, MD, Cardiovascular Laboratory, Presbyterian Hospital, 630 West 168th Street, New York, New York 10032.

Digital subtraction angiography[10–12] markedly enhances the iodine contrast signal, permitting the performance of left ventriculography after intravenous injection of conventional doses of contrast medium. We have found that the contrast enhancement afforded by digital subtraction angiography permits the performance of left ventriculography with very low doses of contrast medium when injected directly into the left ventricle. This method obviates the hemodynamic alterations resulting from intraventricular injection of conventional doses of contrast material. The present study was designed to validate the accuracy of digital left ventriculography for measurement of left ventricular volumes and regional wall contraction in comparison with conventional left ventriculography, and to compare the hemodynamic effects resulting from low-dose and conventional-dose intraventricular contrast injections.

## Methods

**Patient protocol:** Digital and conventional left ventriculography was performed at the time of routine cardiac catheterization in 28 patients, 16 men and 12 women with a mean age of 56 years (range 19 to 74). Sixteen patients had coronary artery disease, 6 had valvular heart disease, 4 had congestive cardiomyopathy, and 2 had normal coronary arteriograms. Informed consent for digital ventriculography was obtained from each patient according to a protocol approved by the Institutional Review Board of the Columbia-Presbyterian Medical Center.

Each patient underwent digital left ventriculography performed with diluted (14%) contrast medium and conventional left ventriculography with undiluted contrast medium. Left ventricular pressures were recorded before and after each ventriculogram. Identical volumes (45 ml) and delivery rates (15 ml/s) were used for both diluted and undiluted contrast injections to permit direct comparison of hemodynamic effects.

**System specifications:** The x-ray system consisted of a Philips modular generator, an SRN 10/80 x-ray tube, and a trimodal (6, 10, 14 in) cesium iodide image intensifier mounted on a Poly diagnost A-™ arm and scanned with a Plumbicon video tube. A prototype Philips Digital Vascular Imaging system, which has a 512 × 512 pixel matrix, an 8 bit A/D converter, and 12 bit memory word depth logarithmically amplified and digitized the video signal. During a continuous 6 second exposure, 30 video frames/s were processed and stored on magnetic tape. For frame-by-frame analysis, the digitized images were simultaneously acquired on a 300 track disc recorder, which sampled 1 frame in 3. Subtracted digital ventriculograms were simultaneously displayed on the television monitor during contrast injection, permitting immediate assessment of the adequacy of the study.

**Digital left ventriculography:** Single-plane digital left ventriculograms were recorded in a 30° to 35° right anterior oblique projection during power injection of diluted contrast material through 7 French pigtail catheters positioned in the left ventricular cavity. Seven ml of sodium meglumine diatrizoate (Renografin® 76) was diluted in 43 ml of normal saline solution, mixed thoroughly in the injection syringe of the power injector, and injected at a rate of 15 ml/s for 3 seconds. The injection was not electrocardiographically synchronized with end-diastole. The concentration of diluted contrast medium used (14%) was found optimal for the adjusted enhancement levels of the digital video system used in this study. Lower concentrations (10%) provided inadequate opacification, and higher concentrations (20%) resulted in excessive opacification.

The kVp (55 to 60 range) and mA (100) were first adjusted on preliminary exposures of 80 ms. An initial digitized image, or mask frame, was recorded in the continuous mode over 320 ms during held inspiration. Immediately afterwards, the digital left ventriculogram was recorded in the same mode, and the contrast injection was delayed until 1 nonopacified cardiac cycle was recorded. During the contrast injection, fully subtracted and enhanced images were continuously displayed for 6 seconds at 30 frames/s.

The digitized subtracted images were then replayed from the disc frame by frame, and the frames showing end-diastole and end-systole were selected visually from the first fully opacified cardiac cycle. Cycles with premature contractions and postectopic cycles were excluded. Postprocessing was done in the serial mode with dual video screens to further enhance image quality. The end-systolic image from the opacified cardiac cycle was displayed on 1 video screen, and the frames of the nonopacified cardiac cycle, recorded just before contrast injection, were displayed on the second video screen. The frames from the nonopacified cardiac cycle were subtracted sequentially frame by frame from the end-systolic opacified image until the corresponding end-systolic image was located, which resulted in the least misregistration. This second order subtraction image was then stored in computer memory, and the enhancement level adjusted appropriately for recording the image on radiographic film. This procedure was repeated for selecting and enhancing the end-diastolic image. The end-diastolic and end-systolic frames were recorded on single emulsion Kodak MR-1 film (8 × 10 in) with a multiformat video camera system (Matrix Instruments). As a spatial reference, a 1 cm crosshatched radiopaque grid was positioned at the level of the left ventricle and recorded on the magnetic disc in serial mode. This digital grid image was also transferred to computer memory and recorded on 8 × 10 in film.

**Conventional left ventriculography:** Conventional contrast ventriculograms were recorded 10 minutes after the digital left ventriculograms in the identical right anterior oblique projection without altering the patient's position or the height of the image intensifier or the angiographic table. During held inspiration, 45 ml of undiluted sodium meglumine diatrizoate was power-injected through the 7 French pigtail catheter at a rate of 15 ml/s. The ventriculogram was recorded on 35 mm cineangiographic film at 32 frames/s using the 10-inch field size of the image intensifier. Following ventriculography, the radiopaque crosshatched 1 cm grid was recorded at the level of the left ventricle as a spatial reference. End-diastolic and end-systolic cineangiographic frames were selected by the same criteria used for digital ventriculography.

**Left ventricular analysis:** Left ventricular silhouettes in end-diastole and end-systole were traced manually from the digital and cineangiographic ventriculograms using a computer-assisted light pen. The long axis of the left ventricle was measured as the longest straight line from the apex to the midpoint of the aortic valve. End-diastolic and end-systolic volumes were calculated using the single-plane, area-length method of Sandler and Dodge.[13] Digital and conventional ventriculograms were analyzed separately by a blinded investigator, who was unaware of the results of each ventriculographic analysis.

Segmental left ventricular contraction patterns were analyzed quantitatively by the method of Herman et al.[14] The

long axis of the ventricular silhouettes was quadrisected, and percent shortening from end-diastole to end-systole was calculated for the following transverse hemiaxes: anterobasal, anterolateral, apical, diaphragmatic, and posterobasal. In addition, percent shortening of the long axis was calculated.

**Hemodynamic measurements:** Left ventricular pressures were measured through fluid-filled 7 French pigtail catheters inserted percutaneously into the femoral artery. Pressures were recorded on a switched-beam oscilloscopic recorder using Statham P23Db pressure transducers positioned to a zero level 5 cm below the sternal angle. Left ventricular systolic and end-diastolic pressures were recorded immediately before each digital and conventional left ventriculogram. Twenty to 30 seconds after each ventriculogram, pressure measurements were repeated after the catheter was flushed with heparinized saline solution. Left ventricular systolic pressure was calculated as the peak systolic pressure averaged over 10 seconds. The end-diastolic pressure was determined as the mean of the diastolic pressure coinciding with the R wave, averaged over 10 seconds.

**Statistical analysis:** Correlations between ventriculographic measurements were tested by linear regression.[15] Differences between hemodynamic variables measured before and after contrast injections were evaluated by Student's paired *t* test.[16]

## Results

**Digital left ventriculography:** Digital subtraction left ventriculograms, displayed in real time from magnetic tape at 30 frames/s, appeared qualitatively identical to cineangiographic left ventriculograms. Representative end-diastolic and end-systolic digitized images of the left ventricle, resulting after second-order mask subtraction, are shown in Figure 1, compared with end-diastolic and end-systolic frames of the conventional cineangiographic left ventriculogram recorded in the same patient. The cavity of the left ventricle is as well opacified on the digitized ventriculogram as on the conventional ventriculogram, and the margins of the left ventricle are seen equally well. Second-order mask subtraction enhanced image quality and contrast density considerably.

**Left ventricular volumes:** Left ventricular angiographic end-diastolic volumes ranged from 58 to 359 ml, and end-systolic volumes ranged from 22 to 305 ml. The mean end-diastolic volume calculated from digital left ventriculograms (160.6 ± 89 ml) did not differ significantly from the mean end-diastolic volume calculated by conventional left ventriculography (152.5 ± 90 ml).

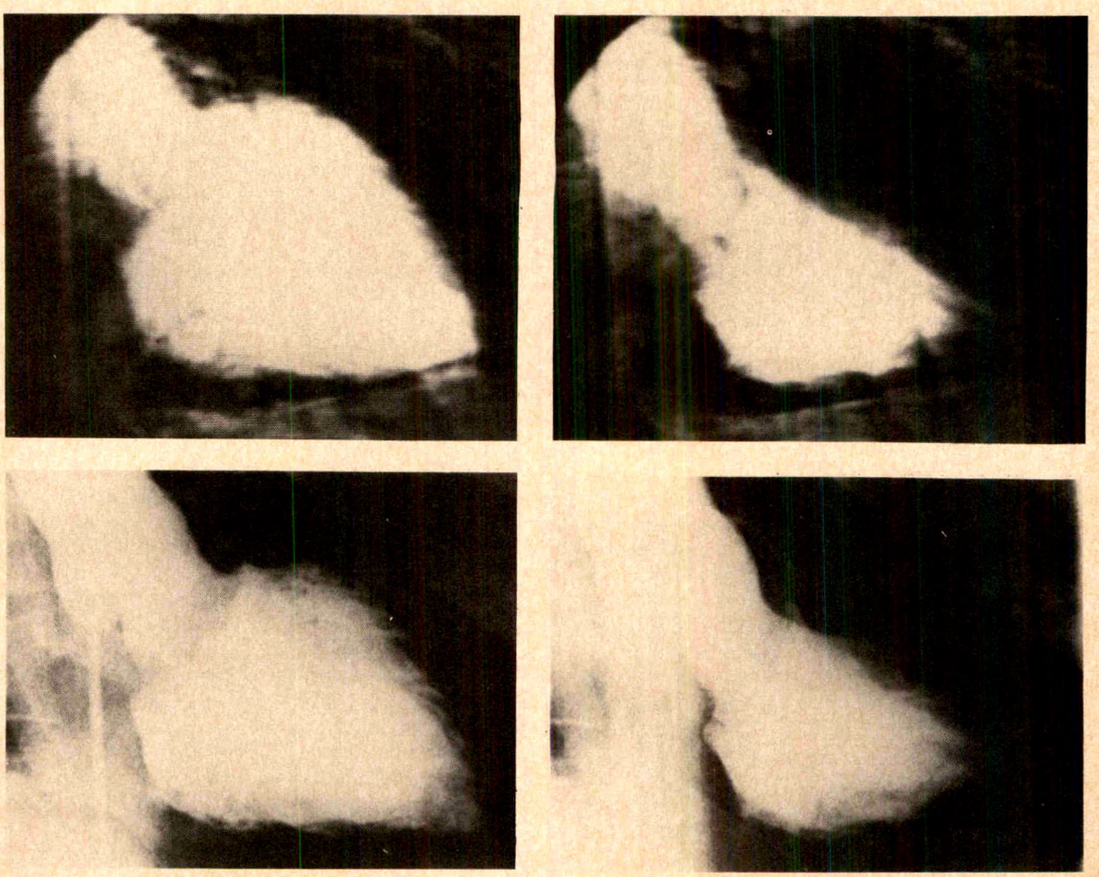

**FIGURE 1.** End-diastolic (**top left**) and end-systolic (**top right**) frames of a representative digital left ventriculogram recorded during intraventricular injection of diluted contrast medium. End-diastolic (**bottom left**) and end-systolic (**bottom right**) frames of the conventional cineangiogram of the left ventricle recorded in the same patient.

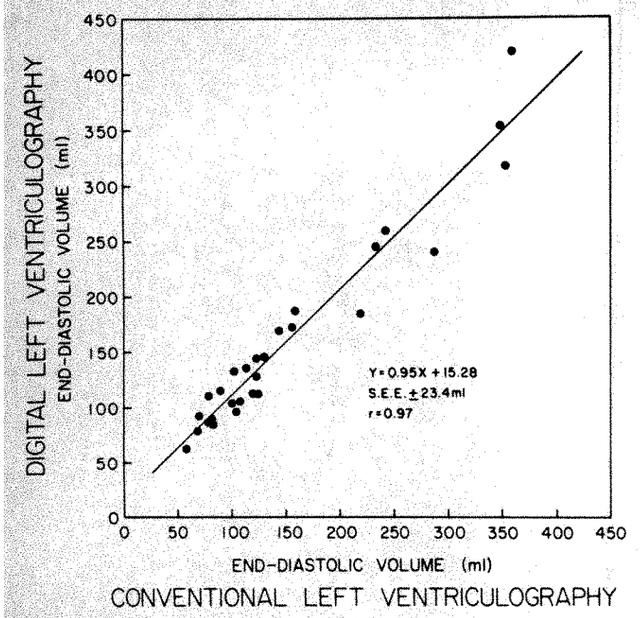

**FIGURE 2.** Correlation for left ventricular end-diastolic volumes calculated from digital and conventional left ventriculograms.

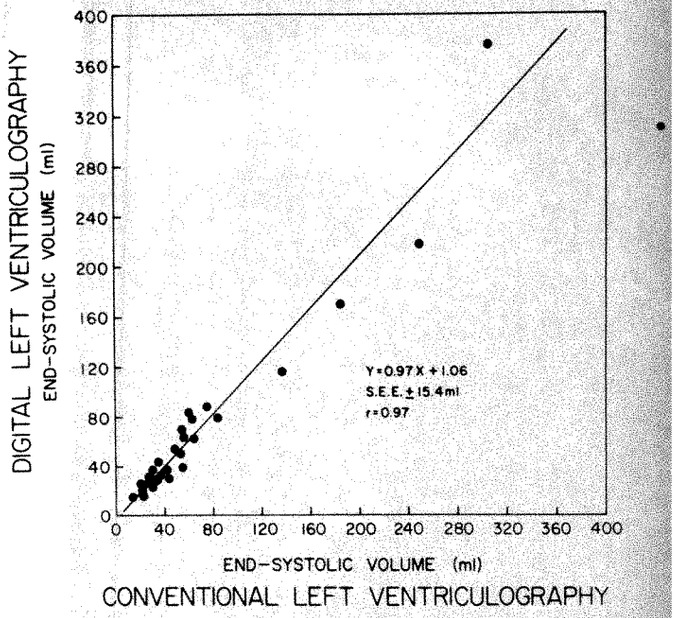

**FIGURE 3.** Correlation for end-systolic volumes calculated from digital and conventional left ventriculograms.

Similarly, mean end-systolic volumes (71.3 ± 75 versus 68.1 ± 70 ml), mean left ventricular stroke volumes (91.1 ± 48 versus 84.5 ± 45 ml), and mean left ventricular ejection fraction (61 ± 18 versus 60 ± 16%) calculated from digital and conventional left ventriculograms did not differ significantly.

Regression analysis of end-diastolic and end-systolic volumes calculated from digital (D) and conventional (c) left ventriculograms is presented in Figures 2 and 3. The regression equation relating end-diastolic volumes was $EDV_D = 0.95\ EDV_c + 15.3$ ml (r = 0.97, SEE 23.4 ml), indicating a close linear correlation. For end-systolic volumes, the regression equation was $ESV_D = 0.97\ ESV_c + 1.06$ (r = 0.97, SEE 15.4 ml).

Regression analysis of left ventricular stroke volume and ejection fraction is presented in Figures 4 and 5. The regression equation relating stroke volumes calculated from digital and conventional left ventriculograms was $SV_D = 1.03\ SV_c + 3.8$ ml (r = 0.95, SEE 14.7 ml). The regression equation relating left ventricular ejection fraction was $EF_D = 1.09\ EF_c - 4.5\%$ (r = 0.97, SEE = 3.8%).

The reproducibility of ventricular volume measurements was determined for conventional and digital ventriculograms by repeating ventriculographic analyses for a subset of 14 patients. The following correlation coefficients resulted from repeated analysis of conventional ventriculograms: EDV 0.98, ESV 0.99, SV 0.97, and EF 0.97. For repeated analysis of digital ventriculograms, the following correlation coefficients resulted: EDV 0.98, ESV 0.95, SV 0.97, and EF 0.99.

**Regional left ventricular wall motion:** The percent chordal shortening values for 140 hemiaxes and the 28 measurements of long-axis shortening calculated

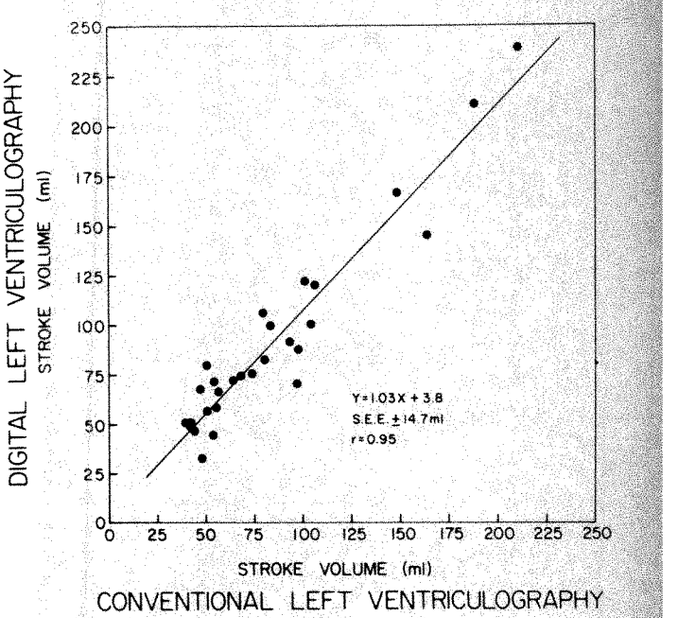

**FIGURE 4.** Correlation for stroke volumes calculated from digital and conventional left ventriculograms.

from digital left ventriculograms and conventional ventriculograms are compared in Figure 6. The correlation coefficient (r = 0.81) and SEE (±11.5%) indicate a moderate correlation. Correlation coefficients for individual hemiaxes were as follows: anterobasal (r = 0.72), anterolateral (r = 0.77), apical (r = 0.86), diaphragmatic (r = 0.76), posterobasal (r = 0.64), and long-axis shortening (r = 0.76).

**Hemodynamic changes:** After injection of undiluted contrast medium for conventional ventriculography, mean systolic left ventricular pressure decreased from 133.0 ± 31 to 123.5 ± 27 mm Hg ($p < 0.01$) and mean left ventricular end-diastolic pressure increased from 12.0 ± 7 to 16.9 ± 10 mm Hg ($p < 0.001$). After injection of diluted contrast medium for digital ventriculography, mean systolic left ventricular pressure (133.6 ± 28 versus 131.2 ± 28 mm Hg) and left ventricular end-diastolic pressure (13.0 ± 8 versus 13.3 ± 8 mm Hg) were not significantly changed. Heart rate and peak left ventricular dP/dt were not changed significantly after either conventional or digital left ventriculography.

Fifteen of the patients experienced a warm flushed sensation after injection of undiluted contrast medium. Only 1 of the patients had any discomfort after injection of diluted contrast medium. Isolated ventricular premature contractions occurred in 4 patients during injection of undiluted contrast medium and in 3 patients during injection of diluted contrast medium. Two patients with congestive cardiomyopathy tolerated low-dose diluted contrast injections well but developed pulmonary edema after full-dose injections of undiluted contrast medium.

## Discussion

Digital subtraction angiography enhances contrast density by a factor >8,[11] enabling the performance of angiography with markedly reduced doses of contrast medium. The present study demonstrates that digital subtraction angiography permits the performance of contrast left ventriculography with very low doses of contrast medium. This new approach to left ventriculography provides high resolution ventriculograms for accurate measurement of left ventricular volumes, stroke volume, and ejection fraction.

Low-dose contrast ventriculography has several advantages. First, as shown in the present study, low-dose intraventricular contrast injections do not cause the hemodynamic disturbances which result from injection of conventional doses of contrast material. Second, low-dose contrast injections should obviate the risk of nephrotoxicity associated with larger doses. Third, patients do not experience any discomfort during low-dose injections. Fourth, since the data are in digital form, digitized images can be readily analyzed by computer, facilitating videodensitometric quantification of ventricular function. This approach may enable measurement of left ventricular ejection fraction independent of geometric assumptions.[17]

On the basis of these considerations, digital left ventriculography with diluted contrast medium is suitable for serial ventriculography for assessment of the effect of therapeutic interventions on left ventricular function. The low doses of contrast medium made possible by digital left ventriculography are clinically advantageous in patients with severe congestive heart failure, impaired liver function, diabetes, or renal insufficiency, who tolerate multiple contrast injections poorly.[18,19] Digital left ventriculography will be useful in catheterization laboratories without biplane angiography facilities, since multiple digital angiograms can be performed in different projections with low total doses of contrast medium and minimal patient discomfort.

Other investigators have recently described digital left ventriculography performed with 5 to 10 ml of undiluted contrast medium injected into the left ventricle over 1 or 2 seconds.[20,21] In our experience, rapid injection of small doses of undiluted contrast medium results in incomplete opacification of the left ventricular cavity due to inadequate mixing. We found that dilution of the contrast medium with saline solution permitted injection of larger volumes over a longer period and resulted in full opacification of the ventricle for several cardiac cycles. The quality of the resulting left ventriculograms was excellent, and measurements of end-diastolic volume, end-systolic volume, stroke volume, and ejection fraction correlated highly with values measured by conventional contrast left ventriculography.

A disadvantage of the prototype digital video system used in the present study, however, is the limited recording capacity of the magnetic disc. Although digital frames were acquired and displayed in a cineangiographic format at 30 frames/s on magnetic tape, the disc recorder used for selecting end-systolic and end-diastolic frames was capable of recording only 1 frame in 3. Hence, the effective frame rate was 10/s. Frame rates of this magnitude are marginally adequate for measuring left ventricular volumes[22] but are inadequate for accurately measuring segmental left ventricular contraction. This limitation is the most probable explanation for the moderate correlation observed between segmental left ventricular contraction assessed by digital ventriculography and conventional ventriculog-

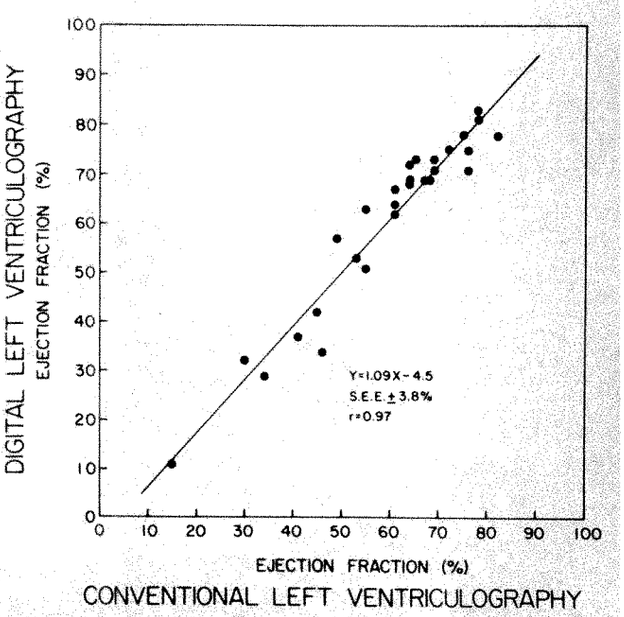

**FIGURE 5.** Correlation for ejection fractions calculated from digital and conventional left ventriculograms.

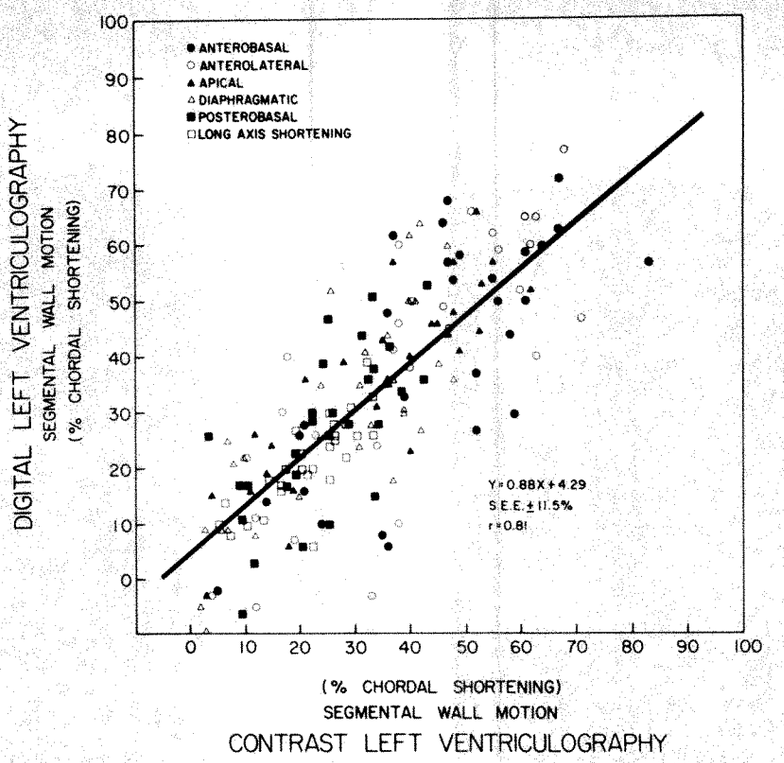

**FIGURE 6.** Percent chordal shortening for 5 left ventricular hemiaxes and the long axis of the left ventricle, measured from digital and conventional left ventriculograms.

raphy. Real-time video discs are available which are capable of acquiring 30 frames/s. Use of these discs will improve the accuracy of quantification of segmental left ventricular contraction by digital ventriculography.

One advantage of the digital video processor used in the present study is that it produces fully processed, time-subtracted images immediately available for viewing and for recording on radiographic film. The capability for second-order subtraction of individual frames from the nonopacified cardiac cycle recorded just before contrast injection was found to enhance contrast density and image quality considerably. Furthermore, geometric distortion at the borders of the fluoroscopic field is eliminated with the present system by the curvature of the output fiberoptics of the image intensifier. This digital subtraction system will have other useful applications in cardiovascular angiography, particularly for aortography with small doses of contrast medium injected selectively.

The effect of intraventricular contrast injections on the accuracy of angiographic measurements of left ventricular volumes is controversial. Studies in animal models have shown that end-diastolic and end-systolic volumes are increased immediately after intraventricular contrast injections.[4,7] In patients undergoing contrast left ventriculography, Carleton[7] reported a significant increase in end-diastolic volume by the third cycle after contrast injection. Hammermeister and Warbasse,[23] however, found no significant change in left ventricular volumes measured sequentially after contrast injection. To measure left ventricular volumes in patients without injection of contrast medium, Vine et al[24] introduced a method for calculating left ventricular volumes radiographically from metallic epicardial markers implanted during coronary artery surgery. Using this approach, they found that ventricular volumes were not affected by injection of contrast medium through the sixth beat.

The high correlations observed in the present study for ventricular volumes measured during the high- and low-dose contrast injections support the conclusion of Vine et al.[24] There was no evidence in the present study that injection of conventional doses of contrast medium significantly altered left ventricular volumes. Furthermore, the changes in left ventricular pressure caused by injection of standard doses of contrast medium were measured 20 to 30 seconds after completion of ventriculography, and thus would be unlikely to influence volume measurements.

# In Vivo Ultrasonic Tissue Characterization of Human Intracardiac Masses

STEPHEN E. GREEN, MD, LINDA F. JOYNT, PhD, PETER J. FITZGERALD, MSEE, DAVID S. RUBENSON, MD, and RICHARD L. POPP, MD

**Interactions between an ultrasonic signal and cardiac tissue have been used to characterize the histologic state of myocardium in vitro. To assess the utility of in vivo ultrasonic tissue characterization, stochastic analysis was applied to the digitized echocardiographic signals from 15 patients with 2-dimensional echocardiograms suggesting intracardiac masses. Ten subjects with echocardiograms suggesting mural thrombi underwent subsequent surgery or necropsy, which confirmed thrombi in 6 and revealed no thrombi (designated artifact) in 4. Five other patients had intracardiac tumors. The amplitudes within the digitized ultrasonic signals were displayed as histograms, which were described by a parameter k that represented the degree to which each histogram departed from a totally random probability density function. In 5 of 6 thrombi, k = 0, but in all 4 artifacts, k >0. The sixth thrombus had k = 0.5 due to the specular effect of the interface between the thrombus' 2 lobes. All 5 tumors had k >0. Ultrasonic tissue characterization using a stochastic analysis of backscatter can be performed in vivo and helps differentiate thrombus from artifact and tumor in the heart.**

The role of echocardiography in cardiac diagnosis continues to evolve as the technology and our understanding of the properties of ultrasound increase. Current clinical use of echocardiography relies mostly on images or patterns of motion formed by signals reflected off tissue surfaces. Although gray-scale ultrasonography provides visual "texture" to the tissue encompassed by such surfaces, the signal from the intervening tissue is usually not analyzed quantitatively. However, the interactions between internal tissue components and an ultrasonic signal can be analyzed to characterize the histologic state of normal and diseased organs,[1] as studies of the breast,[2,3] liver,[4,5] and eye[6] have demonstrated. In vitro studies of cardiac muscle have been performed,[7–11] but in vivo characterization of human cardiac tissue in a clinical setting is only beginning.[12] We undertook the present study to assess the ability of in vivo ultrasonic tissue characterization to differentiate intracardiac masses of varying histologic types and to eliminate common sources of error in their diagnosis.

## Methods

We attempted ultrasonic tissue characterization in 22 patients with clinical, 2-dimensional echocardiographic evidence of intracardiac thrombi. We excluded 12 subjects because of the lack of subsequent surgery or necropsy in 8 and inability to obtain sufficient data for tissue characterization in 4. The remaining subjects, who had technically adequate characterization studies and underwent cardiotomy or necropsy within days of tissue characterization, were included in the study. The decision to operate was made on clinical grounds, independent of echocardiographic findings. The subjects in whom no thrombus was found on anatomic examination were believed to have spurious echoes (technical artifact) causing suspicious echocardiographic images. Seven subjects had had myocardial infarction with ventricular aneurysm, 2 had congestive cardiomyopathy, and 1 had mitral stenosis with a suspected left atrial thrombus. We also performed in vivo ultrasonic tissue characterization in 5 additional consecutive patients with echocardiographic evidence of left atrial tumor. Four of these subjects later underwent surgery; the fifth refused operation. One patient with an atrial tumor confirmed at surgery had coexistent mitral stenosis. Preoperatively, the atrial mass could not be distinguished from thrombus by clinical or echocardiographic means.

Two-dimensional echocardiograms were obtained from commercially available sector scanners (V-3000, Varian Associates, Palo Alto, California; 77020A, Hewlett-Packard, Andover, Massachusetts) with focused, 2.25 MHz transducers coupled to a high-speed data acquisition system (Fig. 1). The region of the suspected thrombus or tumor was imaged in the

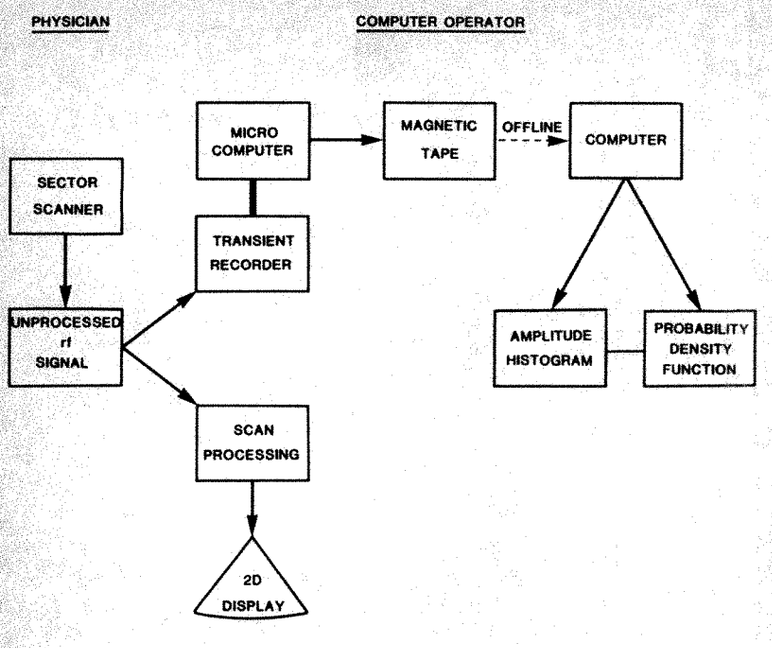

**FIGURE 1.** Diagram of data acquisition and analysis. The physician obtains the subject's echocardiogram, and the computer operator controls data sampling. The unprocessed signal is stored on tape and transferred to computer, where amplitude histograms and probability density functions are derived off-line. 2D = 2-dimensional; rf = radiofrequency.

apical 4-chamber or parasternal long- or short-axis projections,[13] and the M-mode cursor was directed through the suspected mass (Fig. 2). The unprocessed radiofrequency (rf) signal from the cursor-selected scan line was sampled at 20 MHz and digitized with a Biomation 8100 Transient Recorder under minicomputer control (Z-2, Cromemco, Mountain View, California). The signal was sampled for 40 pulses, with each sample requiring less than 1.2 ms and containing 500 to 1,000 data points. The data were transferred to a large, slow-speed buffer, where they were stored until processed off-line by a computer (2100-A, Hewlett Packard, Palo Alto, California). The unprocessed rf signal was displayed as amplitude versus tissue depth, as in Figure 2. The operator selected the depth corresponding to the anatomic region of interest, and the computer derived a histogram representing the distribution of component amplitudes of the digitized signal from that region. Each amplitude distribution was described by a parameter k, corresponding to the degree to which the histogram departed from the probability density function expected from a collection of small, random, independent scatterers. Thus, a random array of scatterers reflects a signal with an amplitude histogram described by $k = 0$, whereas an array of scatterers with nonrandom or correlated amplitudes is characterized by $k > 0$.[14] (see Appendix.) We attempted to differentiate thrombus from tumor and artifact on the basis of the amplitude histograms of their backscattered signals. We modeled thrombus as a random array of small, statistically independent scatterers. Tumor and artifact were modeled as random, independent, small scatterers mixed with nonrandom, correlated scatterers.

## Results

Direct visual examination of the heart at operation confirmed the presence of intracardiac thrombi in 6 of the 10 subjects with suspected thrombi and revealed no thrombus in the other 4. Thrombi were located in apical left ventricular aneurysms in 3 patients, in apical regions of myopathic hearts in 2, and in a posterobasal aneurysm in 1. Three of the 4 spurious images were located in the region of apical aneurysms. The fourth spurious image, in a patient with stenosis of the mitral valve, was located in the left atrium. The 4 subjects with echocardiographic evidence of left atrial tumor who underwent surgery were found to have myxomas.

Figures 2 through 4 show data obtained by in vivo tissue characterization of 3 suspected intracardiac masses. Figure 2 is a composite of data from a patient with a left ventricular thrombus. The cursor passes through the thrombus indicating the scan line that contains the unprocessed rf signal that is sampled. The portion of the signal reflected from the region of interest is digitized and displayed as a histogram of the component amplitudes of the backscattered signal. The amplitude histogram of thrombus fits a probability density function with $k = 0$, implying a randomly spaced, independent collection of scatterers. In contrast, Figure 3 depicts data obtained from a subject with a similar-appearing intracavitary image on 2-dimensional study, but backscatter amplitude analysis revealed $k > 0$, suggesting that there is a nonrandom, nonindependent component to the scatterer architecture. The subject had no thrombus at surgery, and the image was classified as artifact. Figure 4 shows data obtained from a subject with a left atrial myxoma. Tissue character-

**TABLE I Summary of Data***

| Thrombus | | Myxoma | | Artifact | |
|---|---|---|---|---|---|
| Subject | k | Subject | k | Subject | k |
| 1 | 0 | 1 | 2.5 | 1 | 1.0 |
| 2 | 0 | 2 | 1.5 | 2 | 1.5 |
| 3 | 0 | 3 | 1.5 | 3 | 2.5 |

| 6 | 0 | ... | ... | ... | ... |

* K is a variable representing the ratio of nonrandom to random features in the probability density function. See Appendix.

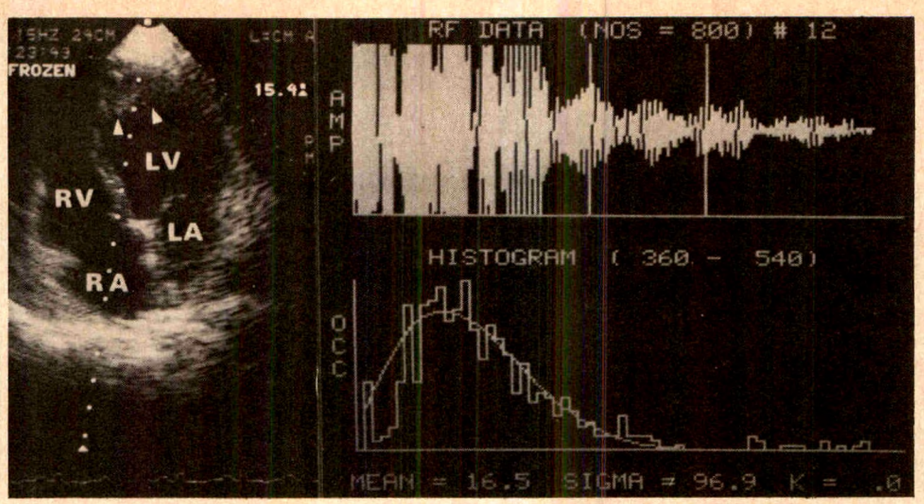

**FIGURE 2.** Composite of data obtained from a patient with an apical left ventricular thrombus confirmed at necropsy. The **left panel** shows a 2-dimensional echocardiographic image in the apical 4-chamber projection. The M-mode cursor passes through the thrombus (**arrows**), identifying the scan line from which the ultrasonic signal is sampled. The **upper right panel** is the 12th of 40 unprocessed signal samples and consists of 800 data points. Signal amplitude is represented on the **ordinate** and tissue depth on the **abscissa**. The operator-determined region of interest is enclosed by 2 **vertical lines**. The **lower right panel** depicts a histogram representing the number of occurrences (**ordinate**) of the digitized component amplitudes (**abscissa**) of the signal from the region of interest. A theoretical probability density function, derived from the mean amplitude and variance of the signal, is superimposed on the histogram. The histogram is described by k = 0, suggesting a random, independent collection of small scatterers. AMP = amplitude; LA = left atrium; LV = left ventricle; OCC = number of occurrences of digitized component amplitude; RA = right atrium; rf = radiofrequency; RV = right ventricle.

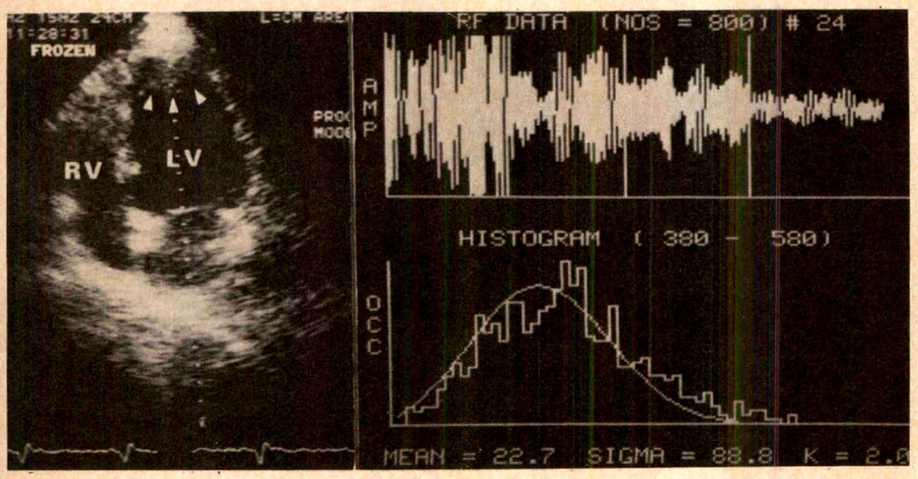

**FIGURE 3.** Composite of data from a subject with an apical image similar to that seen in Figure 2. The **left panel** shows the 2-dimensional display, with the suspected mass identified by **arrows.** The **upper right panel** depicts the unprocessed radiofrequency signal. The **lower right panel** represents the histogram and probability density function derived from the component amplitudes of the signal. The probability density function suggests a correlated component within the signal (k = 2.0). This subject had no thrombus at surgery and the apical echoes represented artifact. Abbreviations as in Figure 2.

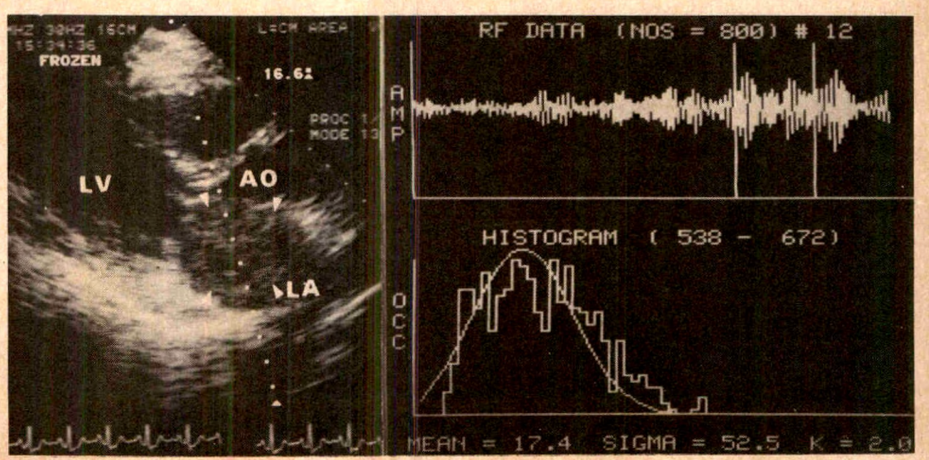

**FIGURE 4.** Composite of data from a subject with a left atrial myxoma. The **left panel** shows a parasternal long-axis 2-dimensional echocardiographic image. The M-mode cursor passes through the mass (**arrows**) in the left atrium. The **upper and lower right panels** depict data from the unprocessed and digitized radiofrequency signal, as in Figure 2. The probability density function (k = 0) suggests a correlated component within the signal. AO = aortic root; other abbreviations as in Figure 2.

ization suggests a nonindependent scattering arrangement with $k > 0$.

Data for the entire study group are summarized in Table I. Five of the 6 patients with thrombi had probability density functions with $k = 0$. One patient who had $k = 0.5$ had a small, bilobed thrombus, and the interface between lobes resulted in a backscattered signal with nonrandom characteristics. All subjects with artifact or myxoma had amplitude probability density functions with $k > 0$. Although k is a continuous variable, it is rounded to increments of 0.5 in Table I.

## Discussion

Initial applications of cardiac ultrasound were limited to descriptive identification of normal and pathologic cardiac structures and their motion. Subsequently, quantitative echocardiographic applications, such as determination of chamber size and wall thickness, were developed. Most standard ultrasonic techniques use specular reflections from interfaces having different acoustic impedance, with little emphasis on the tissue enclosed by such interfaces. However, the interaction between an ultrasonic beam and tissue is dependent on the tissue's physical properties and can result in a characteristic ultrasonic "signature" that varies with the histopathologic state of the tissue.

Although attempts at characterizing tissue histology on the basis of an ultrasonic examination date back at least to 1952,[2] quantitative ultrasonic tissue characterization still remains primarily a research tool. Ultrasonographers and engineers continue to explore the ways in which tissue components alter an ultrasonic signal. There is no consensus as to the optimal way to identify and quantitate the interactions between tissue and ultrasound. The interactions most extensively investigated include attenuation of the signal as it passes through tissue[15] and backscattering of the signal as it is reflected from multiple tissue components or scatterers.[16–18] As an ultrasonic wave propagates through a medium, its energy may be attenuated or absorbed by the medium. Different biologic tissues attenuate sound to distinct and different degrees,[15] which may vary with the health of the tissue. For example, in vitro animal experiments demonstrated that early ischemic myocardial injury decreased ultrasonic attenuation whereas attenuation was increased late after injury.[7,8] The early decrease in attenuation may result from tissue edema, but the late increase appears to result from increased collagen content of the infarcted myocardium.[10] However, application of such attenuation measurements to a living human subject is limited. To assess attenuation, the ultrasonic signal must be measured after it has passed through the organ. Current echocardiographic technology has not developed to the point where this can be done easily in the human subject. The study of reflected or backscattered ultrasound is more amenable to current clinical ultrasonic instruments which are engineered to receive a reflected signal returning from the organ studied. In vitro studies of human liver tissue show that, as in the case of attenuation, the quantity and distribution of collagen, fat, and protein in an organ influence the energy of sound reflected back to the transducer.[17] Other in vitro studies showed that myocardial infarction[9] and adriamycin-induced myocardial damage[11] increase the amount of ultrasonic backscatter. This increase in backscatter presumably represents the effect of increased collagen deposition in the involved areas. The ability to identify normal and abnormal noncardiac tissue structure has been demonstrated in vivo. Wells et al[4] noted increased echocardiographic amplitude reflected from a cirrhotic liver as opposed to a normal liver.[4] Sommer et al,[5] using a stochastic approach similar to ours, also noted increased amplitude of echoes reflected from the cirrhotic liver. Furthermore, the amplitude distribution of the cirrhotic liver was broader than normal, reflecting heterogeneity of hepatic structure in cirrhosis. In the same report, the investigators differentiated the spleen involved with advanced lymphoma and the liver with malignant infiltration from the normal spleen and liver. As in cirrhosis, the amplitude and variance of the signal from diseased organs were consistently greater than normal. Despite these exciting preliminary results, ultrasonic tissue characterization has found little clinical use to date, primarily because of difficulties in acquiring data and in applying appropriate mathematical models to in vivo clinical situations.

We undertook the present study to assess the feasibility of applying ultrasonic tissue characterization to human subjects in vivo to assist in the differentiation of intracardiac masses. Two of the most commonly encountered intracardiac masses are mural thrombi and atrial myxomas. Intracardiac thrombi may complicate myocardial infarction,[19,20] congestive cardiomyopathy,[21] and mitral valve disease.[22] The availability of 2-dimensional echocardiography may lead to improved antemortem diagnosis of intracardiac thrombi,[23–25] but pitfalls remain in attempting to make the correct diagnosis.[24,25] Normal or diseased intracavitary structures such as papillary muscles, intramural, or intracavitary calcifications or myocardial scar may be confused with thrombi.[24,25] Specular reflectors may be located in the region of interest or erroneously displayed in the image field because of beam geometry effects.[26] Spurious echoes, possibly representing reverberation from the transducer or from chest wall structures, appear in the near field of many imaging systems. These images may appear visually similar to thrombus. Although the classic, large, layered mural thrombus is easily distinguished from other structures and artifact,[25] subtle abnormalities are more difficult to assess, especially in patients who cannot be imaged from multiple transducer positions.

Atrial myxomas usually have distinct echocardiographic features,[27–29] yet their clinical presentation may be similar to that of intracardiac thrombi, with systemic emboli being manifestations of either.[30] Furthermore, neoplasm may be echocardiographically indistinguishable from thrombus,[31] especially when the tumor is associated with another cardiac disease, as in our patient with coexistent mitral stenosis. Similarly, a pedunculated thrombus may be indistinguishable from myxoma on standard echocardiography.[32]

To provide an objective means of differentiating intracardiac thrombi from commonly encountered artifacts and tumors, we applied a stochastic approach to the analysis of the echocardiographic signals representing the images in question.[14] A received ultrasonic signal is the sum of the echoes from scatterers contained within a given sample volume. Some tissues may be modeled as a great number of individual scatterers of small cross-sectional area relative to the ultrasonic wavelength. These small scatterers represent random variables, and the amplitude of the signal reflected from each scatterer is statistically independent of the signals reflected from all other scatterers. Therefore, the distribution of amplitudes within the received signal will approximate the probability density function expected from an array of random, independent scatterers.[14] The components of thrombus, an interlacing network of fibrin, platelets, erythrocytes, and leukocytes,[33] are small and arranged homogeneously relative to our scanner's ultrasonic wavelength. Thus, thrombus fits the model of many small scatterers randomly spaced in the sample volume, and the component amplitudes of an ultrasonic signal reflected from thrombus should be distributed in the appropriate probability density function. Conversely, myxomas are composed of cells, strands of collagen and elastin, foci of calcium, islands of extramedullary hematopoieses, and cystic spaces,[30] resulting in multiple acoustic interfaces that are large relative to the ultrasonic wavelength. The signals returned from various parts of these large reflectors are correlated to a degree and therefore do not fit a totally random, independent probability density function.[14] Similarly, near field and beam geometry artifacts do not represent small, independent scatterers distributed throughout the sample volume. They result from specular, inhomogeneous reflectors and therefore do not manifest a totally random probability density function.

By using stochastic analysis of the amplitudes of the backscattered signals, we noninvasively differentiated thrombus from artifact and myxoma. In 5 of our 6 patients with anatomically proven thrombi, the histograms of backscattered amplitudes approximated random probability density functions, whereas all artifact and myxoma studies demonstrated nonindependent components in their functions. Only 1 patient with thrombus departed from the expected random probability density function. This patient had a bilobed thrombus, and because the individual lobes were too small for accurate analysis, we included the entire bilobed structure in the sample volume. The interface between the lobes created a relatively large, specular reflector, resulting in $k = 0.5$. Although the result is not what would be predicted for typical thrombus, this finding is consistent with the modeled effect of an acoustic interface of large cross-section and illustrates the importance of sampling from the internal structure, and not the surface, of the image being analyzed.

The distinction between mural thrombus and artifact or myxoma is clinically important, because the management and prognosis of each are different. However, the major benefit of this study is the demonstration that echocardiographic tissue characterization can be performed reliably in vivo. This approach may allow differentiation of normal and pathologic cardiac structures and assist in identification of ischemic, infarcted, or myopathic myocardium.

Problems remain in refining the techniques of ultrasonic tissue characterization. The parameter k accurately separates random from nonrandom amplitude distributions. However, k does not differentiate the various types of nonrandom processes. Thus, we could not differentiate, on the basis of k alone, artifact from myxoma. We expect thrombus with discrete calcification to be a problem, but have not seen this problem so far. Further refinement of our approach is necessary to improve its ability to differentiate various nonrandom processes. Factors that alter the acoustic signal during in vivo imaging include the effects of intervening tissue on the incident and reflected signal, variations in the angle of incidence of the interrogating beam, and cardiac motion.[8,9,12,16,34] By obtaining large quantities of data over a very brief time interval and analyzing them as a function of probability, the stochastic approach minimizes, but does not eliminate, these problems.[12,14,16] The effects of intervening tissue may result in inaccuracy in more subtle efforts at tissue characterization. The resolution of current instruments dictates a minimal target tissue thickness of 1 cm for statistically adequate data collection. For this reason, we currently are unable to perform characterization on smaller structures, such as cardiac valves and small masses. An example of the limitation imposed by sample size is our patient with a bilobed thrombus. We now limit our clinical studies to structures large enough to allow sampling within, but not including, tissue surfaces to minimize the specular effects of these surfaces.

We think it is important to digitize the rf signal before it undergoes electronic processing. Video image processing is used in commercial 2-dimensional echocardiography to produce a pleasing visual image. However, the image modifications distort the information obtained by the interaction of the tissue with sound. The degree of change varies among patients and instruments. By analyzing the signal before it is processed, we may be more able to evaluate the interaction of tissue with sound independent of manipulations by the ultrasonic apparatus.[16]

Our approach to in vivo cardiac tissue characterization uses analysis of the amplitude domain of a reflected ultrasonic signal. Analysis of the frequency domain also conveys information about tissue structure. Biologic tissue consists of regularly arranged structural units. If these repetitive units, such as the portal triads of normal liver, are on the order of the ultrasonic wavelength, their spacing can be measured by analyzing periodic peaks in the signal's frequency spectrum.[5,14] The development of edema, cellular infiltration, or fibrosis may produce changes in tissue spacing and in frequency spectral peaks. Studies in lung,[18] breast,[3] liver, spleen,[5] and eye[6] have demonstrated the use of frequency domain analysis in tissue characterization. Analysis in the frequency domain could be expected to have a similar role in cardiac tissue characterization. However, the structural unit of the heart, the myocardial fiber, is very small

relative to the 0.7 to 1.4 mm wavelength of commercial echocardiographic instruments.[35] Transducers that emit higher frequency signals with wavelengths on the order of myocardial fiber size do not penetrate deeply into the adult chest.[36] Therefore, we have not used frequency analysis in our in vivo studies.

Our study population represents a selected group of patients with a specific clinical problem. Although such selection limits the general applicability of our findings, the selection process is beneficial, because it allows anatomic confirmation of the nature of the echocardiographic signal in question. Our single subject who did not undergo surgery or necropsy had an echocardiographic examination that was classic for myxoma, with attachment of the mass by a stalk to the interatrial septum.

In conclusion, we have shown that echocardiographic tissue characterization, applying a stochastic analysis of the component amplitudes of backscattered ultrasound, can be performed in vivo. The technique provides an exciting new approach to the diagnosis of selected intracardiac masses.

**Acknowledgment:** We thank Gretchen Houd and Margaret Corazza for assistance in the preparation of this manuscript.

## Appendix

The histogram is based on the distribution of amplitudes within the reflected signal and is described as fitting a Raleigh or non-Raleigh probability density function. An array of independent scatterers would be expected to reflect a signal with a mean amplitude ($\bar{a}$) and variance ($\sigma^2$) in the relation $\bar{a}^2 = 2\sigma^2$ (Raleigh). However, if a nonindependent component is included in the array of scatterers, then $\bar{a}^2 = \sigma^2 (2 + k^2)$.[14] Therefore, if $k = 0$, the histogram would be distributed in a fashion resembling a Raleigh probability density function. If $k > 0$, the histogram would resemble a non-Raleigh probability density function. The parameter k is defined as $S/\sigma$. In the modeling of abnormal tissue, S is a constant biasing phasor which represents the effect of larger elastic variations or specular reflectors that lead to a lack of independent scattering. This effect is often superimposed on the homogeneous normal tissue pattern and provides the basis for our differentiation of various kinds of tissue.

# Dialog of the Hearts –by Shakespeare:

**JULIET**

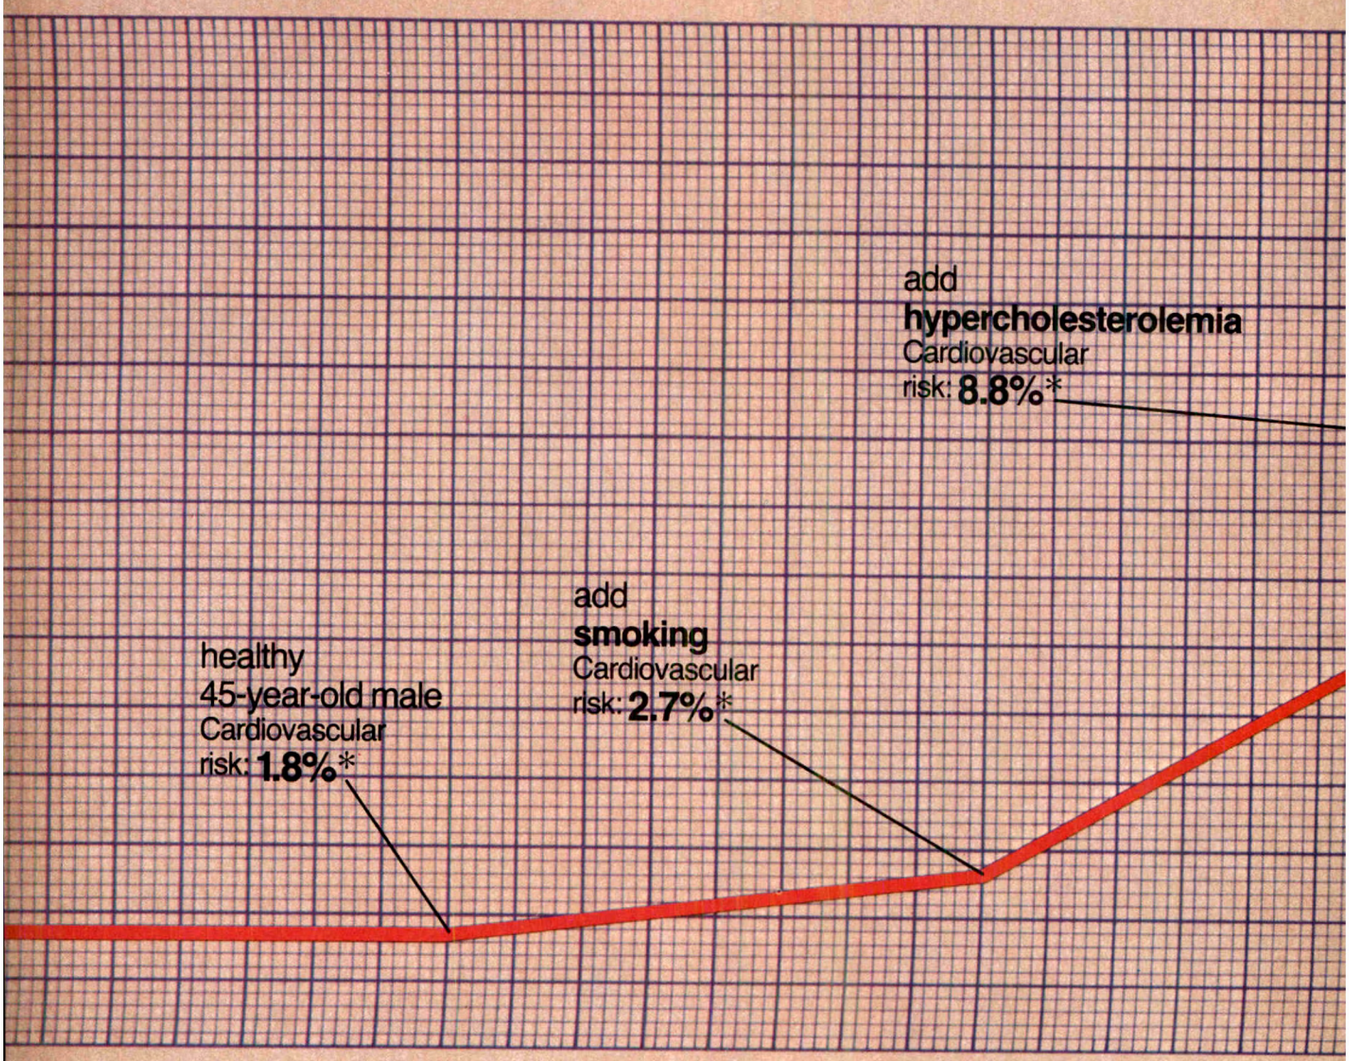
"Wilt thou be gone? It is not yet near day.
It was the nightingale, and not the lark,
That pierced the fearful hollow of thine ear.
Nightly she sings on yond pomegranate tree.
Believe me, love, it was the nightingale.

**ROMEO**

It was the lark, the herald of the morn;
No nightingale. Look, love, what envious streaks
Do lace the severing clouds in yonder East.
Night's candles are burnt out, and jocund day
Stands tiptoe on the misty mountain tops.
I must be gone and live, or stay and die.

**JULIET**

Yond light is not daylight; I know it, I.
It is some meteor that the sun exhales
To be to thee this night a torchbearer
And light thee on thy way to Mantua.
Therefore stay yet; thou need'st not to be gone."



The Dialogue of Romeo and Juliet, Act III, scene V.

**Another Dialog soon to appear—by Siemens.**

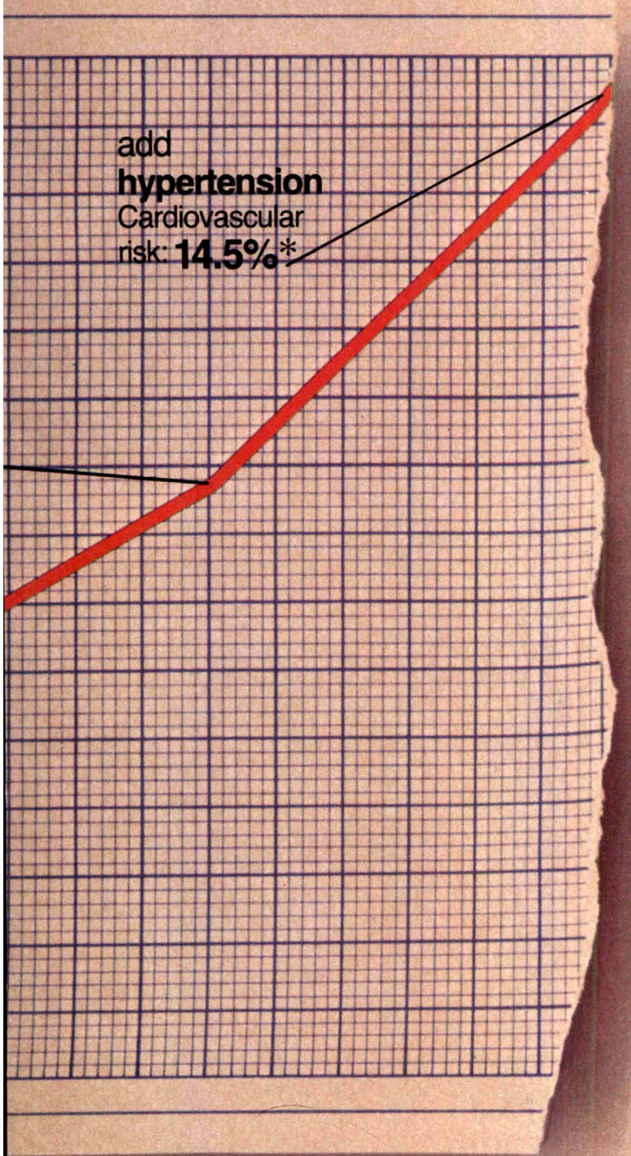
# In hypertensive patients



Other risk factors in CHD are diabetes, obesity, lack of exercise, stress, heredity, sex, age, race.

*Percent equals chances in 100 of developing coronary heart disease within 6 years.

Adapted from *Coronary Risk Handbook:* Estimating risk of coronary heart disease in daily practice. 1973, American Heart Assoc., Inc.

# Consider the Risks

▪ When selecting antihypertensive therapy, clinical consideration should be given to the effects of the specific drug on coronary risk factors. Blood pressure control should be achieved without adversely affecting blood lipids.

## Minipress Effectively Controls Hypertension Without Adverse Effect on Blood Lipids†

▪ Minipress effectively treats hypertension. Patients have benefited from the effectiveness of Minipress in over 5 years of clinical use in this country.[1-5]

▪ Minipress has been shown not to have an adverse effect on blood lipids, according to The Oslo Study and other reports.[6-9] Because Minipress lowers high blood pressure and does not produce lipid changes which are potentially atherogenic, it provides your patient with a net reduction in risk.

†Minipress is not indicated for the treatment of hyperlipidemia.

*Please see Minipress brief summary on following page.*

**Minipress®**
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

© 1982, Pfizer Inc.

**Minipress®** (prazosin HCl) Capsules 1mg, 2mg, 5mg **B.I.D. Dosage Convenience**

**BRIEF SUMMARY**
**MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use***
**INDICATIONS:** MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.
**WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.**
If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.
Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.
More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.
***Usage in Pregnancy:*** Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.
***Usage in Children:*** No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.
**ADVERSE REACTIONS:** The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.
The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established.)
Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.
Cardiovascular: edema, dyspnea, syncope, tachycardia.
Central Nervous System: nervousness, vertigo, depression, paresthesia.
Dermatologic: rash, pruritus, alopecia, lichen planus.
Genitourinary: urinary frequency, incontinence, impotence, priapism.
EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.
Other: diaphoresis.
Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.
In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.
**DOSAGE AND ADMINISTRATION:** The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:
***Initial Dose:*** 1 mg two or three times a day. (See Warnings.)
***Maintenance Dose:*** Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however, a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.
***Use With Other Drugs:*** When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.
**HOW SUPPLIED:** MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

# The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind

# Rheumatology

## A Primary Care Approach

Written by:

**Bruce M. Rothschild, MD**

Director, Division of Rheumatology, University Health Sciences, The Chicago Medical School Chief, Section of Rheumatology, V. A. Medical Center North Chicago, Illinois

**ISBN 0-914316-33-8 430 pp., illus., November 1982, $39.50**

## What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation of the latest techniques in diagnosis and therapeutic interventions of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf
- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease

## Rheumatology: A Primary Care Approach is Not

- a research monograph filled with esoteric information of little use to the practicing primary care physician
- a difficult to follow, badly organized reference tool requiring a thorough knowledge of the subject matter before it can be used effectively
- a massive and verbose dissertation more useful as a door stop than a clinical reference

We know of no other book on rheumatic disease which covers the subject as exhaustively in terms of diagnosis and treatment while avoiding wasting the busy practitioner's time by including information of little interest to the primary care physician. This book emphasizes that information necessary to recognize basic disease processes and their natural history. It provides the reader with the information necessary for making a diagnosis and initiating a plan of treatment. Information on differential diagnosis from the point of view of characteristics which would not fit with a given diagnosis is also provided. It is especially strong on the interpretation of rheumatologic radiology and in its approach to joint examination and assessment of lab results. Rheumatic disease cannot be cured but proper intervention can reduce and sometimes eliminate the attendant disability. This book provides you with the means to diagnose, assess and decide for yourself the necessary intervention.

## From the Preface:

*"More than 15 million individuals in the United States suffer from arthritis, and there are only 3,000 physicians practicing rheumatology. It is evident that the majority of patients receive continuing care from the nonrheumatologist, i.e., the internist, family practitioner, pediatrician and other disciplines in medicine. Therefore, we require concise and authoritative clinical guidelines for the primary care physician. With this as motivation Dr. Bruce Rothschild has skillfully structured a text geared to the particular and immediate needs of the practitioner... This text... is an important contribution to continuing medical education of the clinician. It will be of immediate interest and value to clinicians in a wide variety of specialties and should be of great assistance to the faculties and student bodies of our medical schools. We have long needed this type of approach to primary care of patients with musculoskeletal diseases and we are indebted to the author for his accomplishments."*

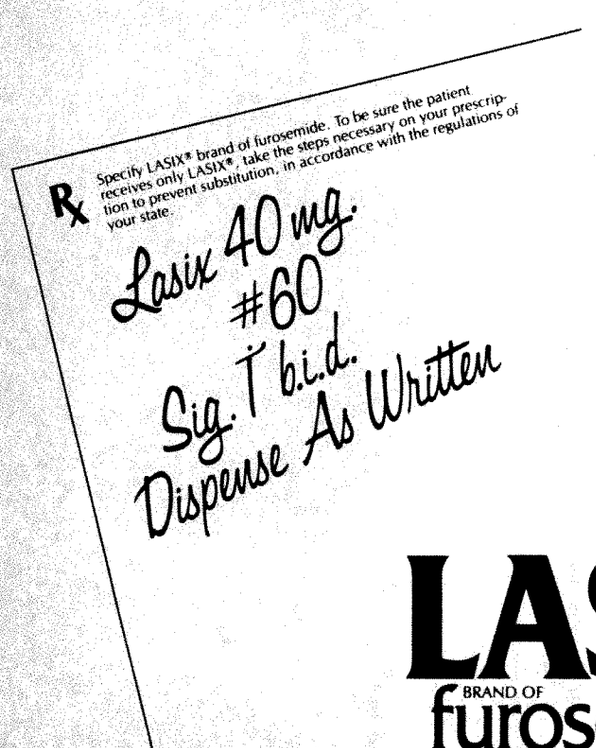
# Avoid any change in the classic digitalis-Lasix® regimen.

BRAND OF furosemide

Every CHF patient on a digitalis-diuretic regimen runs the risk of digitalis toxicity.



But many patients with impaired renal function are particularly vulnerable because their condition may predispose them to a toxic accumulation of digoxin.

These include the diabetic. The geriatric patient. The patient with renal disease. And the patient with advanced CHF who suffers from hepatic as well as renal complications.

Add to this group the patient on multiple medications with possible drug interactions.

Conditions like these that increase the risk of digitalis toxicity are generally outside the physician's control. But two of the most important *preventive* measures which are not outside the physician's control are precise titration of digitalis, *and the consistent use of one diuretic*.

As to the first, the narrow therapeutic-to-toxic range of digitalis is well known and requires no elaboration.

Naturally, increased renal problems necessitate increased vigilance to any signs of toxicity.

### Why the patient should be maintained on LASIX®

The second precaution is the unvarying use of a single diuretic for a given patient (consistent with proper potassium balance). Thus, if the choice is LASIX®—as it is in most successfully managed CHF cases—the logic behind it is beyond debate. LASIX® is the only diuretic for CHF whose effectiveness has been confirmed in no fewer than 6,000 published papers...which offers the most complete range of dosage forms and strengths for precise titration... and is the most widely available brand of furosemide for filling or refilling your prescription anywhere in the United States. In fact, according to a 1980 nationwide survey,[1] office-based physicians affirmed their confidence in LASIX® by naming it as the medication they prescribe most frequently in office practice.

### Protect your LASIX® prescription: prevent substitution

When you prescribe LASIX®, write the phrase "Do not substitute," or whatever your state requires on the prescription.

---

If you are in doubt about a particular generic furosemide, call the offices of the Food and Drug Administration's Bureau of Drugs, Consumer and Professional Relations staff at 301-443-1016.

---

**Reference:** 1. Koch H: Drugs most frequently used in office-based practice: National Ambulatory Medical Care Survey, 1980, Vital and Health Statistics of the Nat Ctr for Health Statistics, No. 78 (May 12) 1982.

**Before prescribing, please consult complete product information, a summary of which appears on the following page.**

# LASIX®

TABLETS: 20, 40 & 80 mg

BRAND OF furosemide

## The diuretic of choice for the digitalized patient.

**Lasix®** (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide) Tablets 20, 40 and 80 mg

**WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.**

**INDICATIONS:** Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

**CONTRAINDICATIONS: Anuria. History of hypersensitivity to the compound.**

**WARNINGS:** Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, $CO_2$, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

**PRECAUTIONS:** As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

**PREGNANCY:** Pregnancy Category C. Furosemide has been shown to cause unexplained maternal deaths and abortions in rabbits at 2, 4 and 8 times the human dose. There are no adequate and well-controlled studies in pregnant women. Furosemide should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

**ADVERSE REACTIONS:** Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

# Cardiac Bioprostheses

## Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

**The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.**

**To order your copy of this important new book use the order form below.**

**edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD**
**ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00**

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

## Who are the editors?

**Lawrence H. Cohn, MD,** is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

**Vincenzo Gallucci, MD,** is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

## Table of Contents

**Section 1 CLINICAL ANALYSIS 1.** The Evolution of the Biological Valve **2.** Heart Valve Replacement with the Hancock Bioprosthesis: A 5-11 Year Follow-up **3.** A 14-Year Experience with Valvular Bioprostheses: Valve Survival and Patient Survival **4.** A Thousand Porcine Bioprostheses Revisited. Do They Conform with the Expected Pattern? **5.** Clinical Durability of the Pericardial Xenograft Valve: 11 Years' Experience **6.** Long-term Results of 159 Porcine Valve Implantations **7.** Mid- and Long-term Evaluation of Porcine Bioprosthetic Valves: A 6-Year Experience

**Section 2 HEMODYNAMICS 8.** Hemodynamic Evaluation of the Hancock Bioprosthesis in the Mitral Position: A 1-7 Year Follow-up **9.** Hemodynamic Evaluation of the Carpentier-Edwards Standard and Improved Anulus Bioprostheses **10.** Hemodynamic Evaluation in Valvular Patients Carrying Low Profile Bioprostheses **11.** Noninvasive Scintigraphic Assessment of Left and Right Ventricular Function in Patients with Bioprosthetic Mitral Valves at Long-term Risk **12.** Orifice View Roentgenography for Evaluation of the Orifice Area of Bioprosthetic Valves

**Section 3 THROMBOEMBOLISM 13.** Alterations in Valvular Surgery: Biological Valves **14.** Early and Late Results of Porcine Bioprostheses Versus Mechanical Prostheses in Aortic and Mitral Positions **15.** Mitral Bioprostheses in 202 Patients with Chronic Atrial Fibrillation, Giant Left Atrium, and Atrial Thrombi: Long-term Results with No Anticoagulation **16.** Thromboembolism and Anticoagulation after Isolated Mitral Valve Replacement with Porcine Heterografts **17.** Preoperative Determinants of Return to Sinus Rhythm after Valve Replacement **18.** Porcine Bioprostheses Versus Mechanical Valvular Substitutes: A Retrospective Comparative Analysis

**Section 4 PEDIATRIC VALVE REPLACEMENT 19.** Valved Conduits: A Panacea for Complex Congenital Heart Defects? **20.** Factors Influencing Late Results of Extracardiac Conduit Repair for Congenital Cardiac Defects **21.** Calcification of Porcine Bioprostheses in Children **22.** Valve Replacement in Children: Biological Versus Mechanical Valves **23.** Bioprosthetic Valve Replacement in Children **24.** Aortic Root Replacement **25.** Conduits Containing Antibiotic Preserved Homografts in the Treatment Of Complex Congenital Heart Defects **26.** Dura Mater Bioprosthesis in Young Patients

**Section 5 EXPERIMENTAL PATHOLOGY 27.** Experimental Evaluation of Bioprosthetic Valves Implanted in Sheep **28.** Role of Mechanical Stress in Calcification of Bioprostheses **29.** Inhibition of Mineralization of Glutaraldehyde-fixed Hancock Bioprosthetic Heart Valves **30.** Prevention of Tissue Valve Calcification by Chemical Techniques

**Section 6 EXPLANT PATHOLOGY 31.** Complications of Replacement of either the Mitral or Aortic Valve or Both by either Mechanical or Bioprosthetic Valves **32.** Pathogenesis and Stages of Bioprosthetic Infection **33.** Structure and Classification of Cuspal Tears and Perforations in Porcine Bioprosthetic Cardiac Valves Implanted in Patients **34.** Pathological Substrates of Porcine Valve Dysfunction **35.** Mode of Failure in 226 Explanted Biological and Bioprosthetic Valves

**Section 7 BIOPROSTHETIC BIOENGINEERING 36.** The Unileaflet Heart Valve Bioprosthesis **37.** Hancock II - An Improved Bioprosthesis **38.** Design and Stress Analysis of Bioprosthetic Valves In Vivo **39.** In Vitro Comparison of the Newer Heart Valve Bioprostheses in the Mitral and Aortic Positions **40.** In Vitro and In Vivo Assessment of the Flow Characteristics of the Xenomedica Porcine Xenograft **41.** The Structure/Function Relationship of Fresh and Glutaralhyde-Fixed Aortic Valve Leaflets

**Section 8 LONG-TERM FOLLOW-UP 42.** Bioprostheses in the Tricuspid Position Versus Valvuloplasty and Mechanical Valves **43.** The Role of Porcine Heterografts in a 14-Year Experience with Tricuspid Valve Replacement **44.** Patient Prosthesis Mismatch in the Tricuspid Position: The Rationale for an Oval Pericardial Tricuspid Valve **45.** The Porcine Bioprosthesis: Failure Rates in the Elderly **46.** Causes of Valve Failure and Indications for Reoperation After Bioprosthetic Cardiac Valve Replacement **47.** Clinical Analysis of the Hancock Porcine Bioprosthesis **48.** Valve Replacement in the Small Anulus Aorta: Performance of the Hancock Modified-Orifice Bioprosthesis **49.** Decreasing Incidence of Porcine Bioprosthetic Degeneration

**Section 9 SUMMING UP 50.** A Cardiologist's Point of View and a Cardiac Surgeon's Point of View

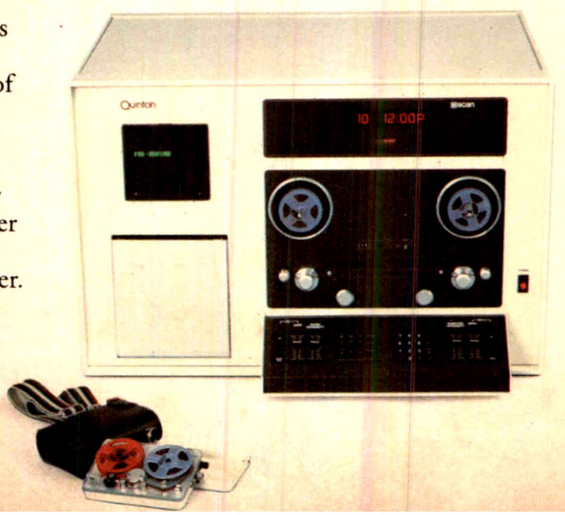
# Q-SCAN TELLS ALL.

Now you can look at every single heartbeat of your patient's day—without wading through complicated charts or relying on mechanical analysis. Because now there's Q-Scan, a new full-disclosure Holter monitoring system from Quinton.

### The information you need in a simple-to-read format.

Q-Scan was designed to make the best use of both your time and expertise. It doesn't make value judgments. Instead it gives you *all* the information you need to make your diagnostic decisions.

In just six minutes, it accurately reproduces every heartbeat from a 24-hour period in a simple-to-read report. You can print the entire 24 hours. Or just those segments that interest you.



Q-Scan gives you a choice of paper, too. A high-speed ultraviolet printer is standard, with a hard copy printer available as an option. An innovation in Holter monitoring, the hard copy printer gives you permanent black and white copies on inexpensive paper.

### Magnification of key data segments.

With Q-Scan, you have the option of taking a closer look at critical time periods. Simply choose the time you'd like to examine. Q-Scan will automatically expand and print those segments. Or, you can evaluate the trace full-size on standard ECG paper, using the optional chart recorder.

For your convenience, Q-Scan also has an optional Arrythmia Detection Program. It gives you an hour by hour summary of abnormal beats and average heart-rate in a simple-to-read report. Abnormal beats are counted and classified in premature and wide, premature and narrow, and couplet, run and non-classified categories.

## INTRODUCING THE HOLTER SYSTEM THAT NEVER MISSES A BEAT.

### Hospital proficiency. Office economy.

With Q-Scan, you can generate top quality diagnostic information right in your office—without special staffing or training. Q-Scan is simple to use. And priced to be affordable for almost any practice. With a lower cost per test than outside services.

Most important, Q-Scan is manufactured with the same quality and dependability that's made Quinton the leader in cardiac electronics.

***For information on Q-Scan or Quinton's Q family of products, call or write Quinton Instrument Company, Cardio Fitness Division, 2121 Terry Avenue, Seattle, Washington, 98121, 1-800-426-0347, Telex 328840. Distributed worldwide.***

# The Pacekeeper™

## For steady maintenance following cardioversion of supraventricular, ventricular, and atrial tachyarrhythmias

- Maintains normal sinus rhythm
- Full quinidine cardiodynamics
- Greater gastrointestinal tolerance than with quinidine sulfate*
- Convenient b.i.d. or t.i.d. dosage

*Bibliography available upon request.

# CARDIOQUIN®
## TABLETS
## (quinidine polygalacturonate)

INDICATIONS AND USAGE: CARDIOQUIN Tablets are indicated as maintenance therapy after spontaneous and electrical conversion of atrial tachycardia, flutter or fibrillation and in the treatment of premature atrial and ventricular contractions, paroxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, and paroxysmal ventricular tachycardia when not associated with complete heartblock. CONTRAINDICATIONS: History of hypersensitivity to quinidine, complete A-V block, complete bundle branch block or other severe intraventricular conduction defects, myasthenia gravis, arrhythmias associated with digitalis toxicity. WARNINGS: In the treatment of atrial fibrillation with rapid ventricular response, use digitalis to control ventricular rate prior to administration of quinidine. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high ventricular rate. This potential hazard may be reduced by digitalization prior to administration of quinidine. *Potentially toxic digoxin plasma levels may occur when quinidine is administered concurrently. Consider reducing digoxin dosage and monitoring for digitalis toxicity.* Evidence of quinidine cardiotoxicity (increased P-R and Q-T intervals, 50% widening of QRS, and/or ventricular ectopic beats or tachycardia) mandates immediate discontinuation of the drug, and/or close clinical and electrocardiographic monitoring. NOTE: Quinidine effect is enhanced by potassium and reduced in the presence of hypokalemia. Quinidine should be used with extreme caution in the presence of incomplete A-V block, since complete block and asystole may result. Quinidine may cause abnormalities of rhythm in digitalized patients; therefore, it should be used with caution in the presence of digitalis intoxication. Caution is also called for in patients exhibiting renal, cardiac or hepatic insufficiency because of potential toxic accumulation of quinidine in plasma. PRECAUTIONS: A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncracy to quinidine. ECG monitoring and determination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are administered. Periodic blood counts and liver and kidney function tests should be performed during long-term therapy.

DRUG INTERACTIONS OF QUINIDINE:

| DRUG | EFFECT |
|---|---|
| With anticholinergic drugs | Additive vagolytic effect. |
| With cholinergic drugs | Antagonism of cholinergic effects. |
| With carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics | Alkalinization of urine resulting in decreas excretion of quinidine. |
| With coumarin anticoagulants | Reduction of clotting factor concentration |
| With tubocurare, succinylcholine and decamethonium | Potentiation of neuromuscular blockade. |
| With phenothiazines and reserpine | Additive cardiac depressive effects. |
| With hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin) | Decreased plasma half-life of quinidine. |
| With digoxin | Increased plasma concentrations of digo (see WARNINGS). |

PREGNANCY: The use of quinidine in pregnancy should be reserved only for those cases whe the benefits outweigh the possible hazards to the patient and fetus. NURSING MOTHERS: T drug should be used with caution due to excretion of the quinidine in breast milk. ADVERS REACTIONS: SYMPTOMS OF CINCHONISM (ringing in the ears, nausea, headaches, and/ disturbed vision) may appear in sensitive patients after a single dose of the drug. GASTROINTE TINAL: Diarrhea, nausea, vomiting, abdominal pain. CARDIOVASCULAR: Widening of QR complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms (including ventricu tachycardia and fibrillation), paradoxical tachycardia, arterial embolism, and hypotension. HEM TOLOGIC: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranul cytosis. CNS: Headache, fever, vertigo, apprehension, excitement, confusion, delirium, a syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydrias blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, nig blindness, scotomata), optic neuritis. DERMATOLOGIC: Rash, cutaneous flushing with intem pruritus, urticaria. HYPERSENSITIVITY REACTIONS: Angioedema, acute asthmatic episo vascular collapse, respiratory arrest, hepatic toxicity. See package insert for Full Prescri information.

ANGINA
INDERAL® (PROPRANOLOL HCl) TODAY CAN TAKE THE CONCERN OUT OF TOMORROW.
Fewer angina attacks, less anginal pain, greater freedom from fear. That's what early use of INDERAL (propranolol HCl) can mean to today's angina patients. INDERAL works to reduce myocardial oxygen demand—by lowering the heart rate... reducing systolic blood pressure... decreasing contractility. Because it helps balance myocardial hemodynamics, INDERAL enables selected patients to do more—with less need for nitroglycerin, less fear of pain. When conventional measures are inadequate, prescribe INDERAL for angina early. INDERAL does more—so your patients may do more.
INDERAL®
(PROPRANOLOL HCl)
The sooner, the better.
Please see following page for Brief Summary of Prescribing Information.

# INDERAL®
## (PROPRANOLOL HCl)

# THE MOST WIDELY PRESCRIBED BETA BLOCKER IN THE WORLD.

The appearance of these tablets is a trademark of Ayerst Laboratories.

*BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)*
**Inderal®** (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

### CONTRAINDICATIONS

1) bronchial asthma, 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless it is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

### WARNINGS

CARDIAC FAILURE: In congestive heart failure, inhibition with beta-blockade carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. In patients already receiving digitalis, propranolol may reduce the positive inotropic action of digitalis and may have an additive depressant effect on AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, in rare instances, cardiac failure has developed during propranolol therapy. At the first sign of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and observed closely. a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Give special consideration to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol should be withdrawn slowly, since abrupt withdrawal may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta-blockade impairs the ability of the heart to respond to reflex stimuli. Except in pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery. In case of emergency surgery, the effects of propranolol can be reversed by administration of beta-receptor agonists such as isoproterenol or levarterenol, but such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), administer with caution, since propranolol may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta-receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Propranolol may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia, especially in patients with labile diabetes. A precipitous elevation of blood pressure may accompany hypoglycemic attacks.

USE IN PREGNANCY: Safe use in human pregnancy not established. Embryotoxic effects have been seen in animals at doses about 10 times the maximum recommended human dose.

### PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if propranolol is administered, since it may occasionally produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

Observe laboratory parameters at regular intervals. Use with caution in patients with impaired renal or hepatic function.

### ADVERSE REACTIONS

*Cardiovascular*: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura. *Central Nervous System*: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. *Gastrointestinal*: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis. *Allergic*: pharyngitis and agranulocytosis; erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress. *Respiratory*: bronchospasm. *Hematologic*: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous*: reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta-blocker (practolol) have not been conclusively associated with propranolol. *Clinical Laboratory Test Findings*: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

### HOW SUPPLIED

TABLETS

--Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprinted with "INDERAL 10," contains 10 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0421-81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NDC 0046-0421-99).

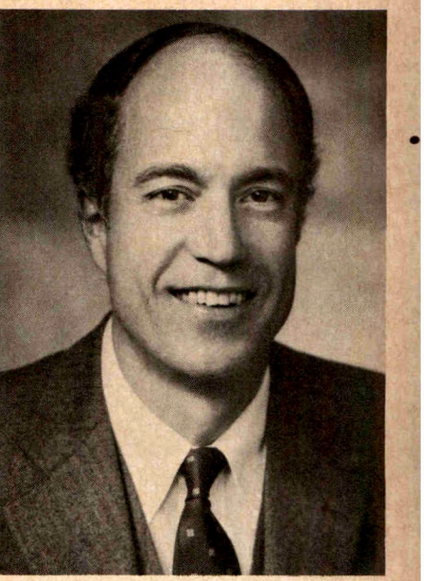
--Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinted with "INDERAL 20," contains 20 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0422-81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0046-0422-99).

--Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinted with "INDERAL 40," contains 40 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0424-81) and 1,000 (NDC 0046-0424-91). Also in unit dose package of 100 (NDC 0046-0424-99).

--Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinted with "INDERAL 80," contains 80 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0428-81) and 1,000 (NDC 0046-0428-91). Also in unit dose package of 100 (NDC 0046-0428-99).

The appearance of these tablets is a trademark of Ayerst Laboratories.

Store at room temperature (approximately 25° C).



INJECTABLE

--Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).

Store at room temperature (approximately 25° C).

# Getting the Manuscript Accepted: Think Like a Lawyer and Cover the Flanks

A manuscript might be viewed as a legal brief in which an author presents logical arguments supporting the contention that he has created and proven a new concept. Reviewers, in a way, are like defense lawyers who attempt to find a flaw in the author's contention. Finding such flaws often casts doubt on other claims of the author or claimant. Indeed, the finding by reviewers or the Editor of *omissions of mention* can be a major stumbling block preventing the acceptance of a manuscript.

A manuscript's quality may be compared to the game of tic-tac-toe, in which 2 players, in turn, fill in 9 compartments, 1 at a time, with X's and O's. The *best paper* fills in all the blocks—covers all the bases—and in addition lines up 3 X's in a row (see the figure below), signifying focus and clarity. A row of zeros indicates that the manuscript provides an essentially negative observation. A manuscript also can have all the blocks filled in but no symbols lined up in a row, indicating a lack of clarity and focus. The *worst paper* fails to fill in 1 or more compartments with either symbol (omissions of mention) and none line up in a row, an indication that the author has failed to mention all the points necessary to prove his case and to focus the points properly.

Editor-in-Chief

# In Hypertension*...When You Need to Conserve $K^+$

# Every Step of the Way

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

†Step 1 usually consists of an initial phase (a diuretic alone), a titration phase (dosage adjustment and/or addition of a $K^+$ supplement or $K^+$-sparing agent), and a maintenance phase (a diuretic alone or in combination with a $K^+$ supplement or $K^+$-sparing agent).

Serum $K^+$ and BUN should be checked periodically (see Warnings).

**Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary.**

* **WARNING**
This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

**Contraindications:** Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

**Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired.** If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum $K^+$ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict $K^+$ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

**Precautions:** Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have been reported. Thiazides have also been shown to increase the paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, 'Dyazide' should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on 'Dyazide' when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with 'Dyazide'. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. 'Dyazide' interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with 'Dyazide', but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and 'Dyazide' should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. 'Dyazide' should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

**Adverse Reactions:** Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances; postural hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on 'Dyazide', although a causal relationship has not been established.

**Supplied: Bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.**

# one-tablet-a-day dosage and... cardioselectivity*

ONE TABLET A DAY

# TENORMIN®

## (atenolol)

Tablets 50 mg

*Cardioselectivity denotes a relative preference for $\beta_1$ receptors, located chiefly in cardiac tissue. This preference is not absolute.

*See last page of this advertisement for brief summary of prescribing information.*

STUART PHARMACEUTICALS

## TENORMIN® (atenolol)

A beta,-selective blocking agent for hypertension.

**INDICATIONS AND USAGE:** TENORMIN (atenolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide-type diuretic.

**CONTRAINDICATIONS:** TENORMIN is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see WARNINGS).

**WARNINGS: Cardiac Failure:** Sympathetic stimulation is necessary in supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, TENORMIN should be administered cautiously. Both digitalis and atenolol slow AV conduction.

**In Patients Without a History of Cardiac Failure:** Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, TENORMIN therapy should be withdrawn.

**Ischemic Heart Disease:** Following abrupt cessation of therapy with certain beta-blocking agents in patients with coronary artery disease, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Therefore, such patients should be cautioned against interruption of therapy without the physician's advice. Even in the absence of overt angina pectoris, when discontinuation of TENORMIN is planned, the patient should be carefully observed and should be advised to limit physical activity to a minimum. TENORMIN should be reinstated if withdrawal symptoms occur.

**Bronchospastic Diseases: PATIENTS WITH BRONCHOSPASTIC DISEASE SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta, selectivity, however, TENORMIN may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta, selectivity is not absolute the lowest possible dose of TENORMIN should be used, with therapy initiated at 50 mg and a beta,-stimulating agent (bronchodilator) made available. If dosage must be increased, dividing the dose should be considered in order to achieve lower peak blood levels.**

**Anesthesia and Major Surgery:** As with all beta-receptor blocking drugs it may be decided to withdraw TENORMIN before surgery. In this case, 48 hours should be allowed to elapse between the last dose and anesthesia. If treatment is continued, care should be taken when using anesthetic agents which depress the myocardium, such as ether, cyclopropane, and trichloroethylene.

TENORMIN, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects on the heart can be reversed by administration of such agents (eg, dobutamine or isoproterenol with caution—see OVERDOSAGE). Manifestations of excessive vagal tone (eg, profound bradycardia, hypotension) may be corrected with atropine (1-2 mg I.V.).

**Diabetes and Hypoglycemia:** TENORMIN should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected. TENORMIN does not potentiate insulin-induced hypoglycemia and, unlike nonselective beta blockers, does not delay recovery of blood glucose to normal levels.

**Thyrotoxicosis:** Beta-adrenergic blockade may mask certain clinical signs (eg, tachycardia) of hyperthyroidism. Abrupt withdrawal of beta blockade might precipitate a thyroid storm; therefore, patients suspected of developing thyrotoxicosis from whom TENORMIN therapy is to be withdrawn should be monitored closely.

**PRECAUTIONS: Impaired Renal Function:** The drug should be used with caution in patients with impaired renal function (see DOSAGE AND ADMINISTRATION).

**Drug Interactions:** Catecholamine-depleting drugs (eg, reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with TENORMIN plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Should it be decided to discontinue therapy in patients receiving beta blockers and clonidine concurrently, the beta blocker should be discontinued several days before the gradual withdrawal of clonidine.

**Carcinogenesis, Mutagenesis, Impairment of Fertility:** Two long-term (maximum dosing duration of 18 or 24 months) rat studies and one long-term (maximum dosing duration of 18 months) mouse study, each employing dose levels as high as 300 mg/kg/day or 150 times the maximum recommended human dose, did not indicate a carcinogenic potential in rodents. Results of various mutagenicity studies support this finding.

Fertility of male or female rats (evaluated at dose levels as high as 200 mg/kg/day or 100 times the maximum recommended human dose) was unaffected by atenolol administration.

**Animal Toxicology:** Chronic studies performed in animals have revealed the occurrence of vacuolation of epithelial cells of Brunner's glands in the duodenum of both male and female dogs at all tested dose levels of atenolol (starting at 15 mg/kg/day or 7.5 times the maximum recommended human dose) and increased incidence of atrial degeneration of hearts of male rats at 300 mg but not 150 mg atenolol/kg/day (150 and 75 times the maximum recommended human dose, respectively).

**USAGE IN PREGNANCY:** Pregnancy Category C. Atenolol has been shown to produce a dose-related increase in embryo/fetal resorptions in rats at doses equal to or greater than 50 mg/kg or 25 or more times the maximum recommended human dose. Although similar effects were not seen in rabbits, the compound was not evaluated in rabbits at doses above 25 mg/kg or 12.5 times the maximum recommended human dose. There are no adequate and well-controlled studies in pregnant women. TENORMIN should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

**Nursing Mothers:** It is not established to what extent this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving atenolol.

**Pediatric Use:** Safety and effectiveness in children have not been established.

**ADVERSE REACTIONS:** Most adverse effects have been mild and transient. Frequency estimates were derived from controlled studies in which adverse reactions were either volunteered by the patient (U.S. studies) or elicited (eg, by checklist—foreign studies). The reported frequency of elicited adverse effects was higher for both TENORMIN and placebo-treated patients than when these reactions were volunteered. Where frequency of adverse effects for TENORMIN and placebo is similar, causal relationship is uncertain.

The following adverse-reaction data present frequency estimates in terms of percentages: first from the U.S. studies (volunteered side effects) and then from both U.S. and foreign studies (volunteered and elicited side effects):

**U.S. STUDIES (% ATENOLOL-% PLACEBO):**

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (0%-0.5%), postural hypotension (2%-1%), leg pain (0%-0.5%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (4%-1%), vertigo (2%-0.5%), light-headedness (1%-0%), tiredness (0.6%-0.5%), fatigue (3%-1%), lethargy (1%-0%), drowsiness (0.6%-0%), depression (0.6%-0.5%), dreaming (0%-0%)

GASTROINTESTINAL: diarrhea (2%-0%), nausea (4%-1%)

RESPIRATORY (See WARNINGS): wheeziness (0%-0%), dyspnea (0.6%-1%)

**TOTALS U.S. AND FOREIGN STUDIES:**

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (12%-5%), postural hypotension (4%-5%), leg pain (3%-1%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (13%-6%), vertigo (2%-0.2%), light-headedness (3%-0.7%), tiredness (26%-13%), fatigue (6%-5%), lethargy (3%-0.7%), drowsiness (2%-0.5%), depression (12%-9%), dreaming (3%-1%)

GASTROINTESTINAL: diarrhea (3%-2%), nausea (3%-1%)

RESPIRATORY (see WARNINGS): wheeziness (3%-3%), dyspnea (6%-4%)

MISCELLANEOUS: There have been reports of skin rashes and/or dry eyes associated with the use of beta-adrenergic blocking drugs. The reported incidence is small and, in most cases, the symptoms have cleared when treatment was withdrawn. Discontinuance of the drug should be considered if any such reaction is not otherwise explicable. Patients should be closely monitored following cessation of therapy.

**POTENTIAL ADVERSE EFFECTS:** In addition, a variety of adverse effects have been reported with other beta-adrenergic blocking agents, and may be considered potential adverse effects of TENORMIN (atenolol).

**Hematologic:** Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

**Allergic:** Fever, combined with aching and sore throat, laryngospasm and respiratory distress.

**Central Nervous System:** Reversible mental depression progressing to catatonia, visual disturbances, hallucinations, an acute reversible syndrome characterized by disorientation of time and place, short-term memory loss, emotional lability with slightly clouded sensorium, decreased performance on neuropsychometrics.

**Gastrointestinal:** Mesenteric arterial thrombosis, ischemic colitis.

**Other:** Reversible alopecia, Peyronie's disease, erythematous rash, Raynaud's phenomenon.

**Miscellaneous:** The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with TENORMIN during investigational use and foreign marketing experience. Furthermore, a number of patients who had previously demonstrated established practolol reactions were transferred to TENORMIN therapy with subsequent resolution or quiescence of the reaction.

**OVERDOSAGE:** To date, there is no known case of acute overdosage, and no specific information on emergency treatment of overdosage is available. The most common effects expected with overdosage of a beta-adrenergic blocking agent are bradycardia, congestive heart failure, hypotension, bronchospasm, and hypoglycemia.

In the case of overdosage, treatment with TENORMIN should be stopped and the patient carefully observed. TENORMIN can be removed from the general circulation by hemodialysis. In addition to gastric lavage, the following therapeutic measures are suggested if warranted:

**Bradycardia:** Atropine or another anticholinergic drug.

**Heart Block (Second or Third Degree):** Isoproterenol or transvenous cardiac pacemaker.

**Congestive Heart Failure:** Conventional therapy.

**Hypotension (Depending on Associated Factors):** Epinephrine rather than isoproterenol or norepinephrine may be useful in addition to atropine and digitalis.

**Bronchospasm:** Aminophylline, isoproterenol, or atropine.

**Hypoglycemia:** Intravenous glucose.

**DOSAGE AND ADMINISTRATION:** The initial dose of TENORMIN is 50 mg given as one tablet a day either alone or added to diuretic therapy. The full effect of this dose will usually be seen within one to two weeks. If an optimal response is not achieved, the dosage should be increased to TENORMIN 100 mg given as one tablet a day. Increasing the dosage beyond 100 mg a day is unlikely to produce any further benefit.

TENORMIN may be used alone or concomitantly with other antihypertensive agents including thiazide-type diuretics, hydralazine, prazosin, and alpha-methyldopa.

Since TENORMIN is excreted via the kidneys, dosage should be adjusted in cases of severe impairment of renal function. No significant accumulation of TENORMIN occurs until creatinine clearance falls below 35 ml/min/1.73 m² (normal range is 100-150 ml/min/1.73 m²); therefore, the following maximum dosages are recommended for patients with renal impairment:

| Creatinine Clearance (ml/min/1.73 m²) | Atenolol Elimination Half-life (hrs) | Maximum Dosage |
|---|---|---|
| 15-35 | 16-27 | 50 mg daily |
| <15 | >27 | 50 mg every other day |

Patients on hemodialysis should be given 50 mg after each dialysis; this should be done under hospital supervision as marked falls in blood pressure can occur.

**HOW SUPPLIED:** Tablets of 50 mg TENORMIN (atenolol): round, flat, uncoated, white tablets with Stuart embossed on one side and NDC No. 105 embossed on the other side are supplied in monthly calendar packages of 28 tablets, bottles of 100 tablets, and unit-dose packages of 100 tablets. Tablets of 100 mg TENORMIN (atenolol): round, flat, uncoated, white tablets with Stuart embossed on one side and NDC No. 101 embossed on the other side are supplied in bottles of 100 tablets and unit-dose packages of 100 tablets.

Protect from heat, light, and moisture. Store unit-dose and calendar packages at controlled room temperature.

# FOR ANGINA PROPHYLAXIS*

## ANNOUNCING

## SUSTAINED RELEASE

2.5, 6.5, 9.0 mg CAPSULES

# NITROSTAT® SR

# (nitroglycerin capsules)

■ complementary therapeutic effect: nitrates and beta-adrenergic blocking agents reduce myocardial oxygen demand by different mechanisms.

**Mechanism I:** Nitrates reduce myocardial oxygen requirement by acting on systemic circulation. Their vasodilator action decreases venous return and systemic arterial resistance, thus improving the balance between the need and supply of oxygen. Reduction in the myocardial oxygen requirement appears to be the major action of nitrates in relieving typical angina. However, selective dilatation of large coronary vessels by nitrates may be the primary mechanism by which they benefit patients with angina due to coronary spasm.[1]

**Mechanism II:** In contrast, beta-blockers block the beta receptor sites in the heart itself. They work by reducing the heart rate and the force of contraction, thereby lowering oxygen demand. In addition to cardiac output and heart rate, blood pressure is also decreased.

Beta-blockers may reduce the oxygen requirement of the heart at any given level of effort by blocking catecholamine-induced increases in heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction.

■ diminished side effects: some of the negative aspects of the effects of each drug are reduced. For example, concomitant nitrates oppose the increased ventricular size, filling pressure, and end-diastolic pressure caused by beta-adrenergic antagonists.[1]

**The effects of NITROSTAT® SR and a beta-blocker are complementary. The result can be improved therapy for angina prophylaxis.**

■ all day and all night prophylactic action with just two or three daily doses*

How Supplied: 2.5-mg and 6.5-mg strengths, in bottles of 60 and 100 capsules. Also, 9.0-mg strength, in bottles of 60 capsules.

Please see next page for brief summary of prescribing information.

**NITROSTAT® SR...Backed by the experience and reputation of PARKE-DAVIS**

*Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indication as follows: Possibly" effective: For the management, prophylaxis or treatment of anginal attacks. Final classification of the less-than-effective indication requires further investigation.

SUSTAINED RELEASE

Before prescribing, please see full prescribing information. A Brief Summary follows:

**INDICATION:** Based on a review of this drug by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indication as follows.

"Possibly" effective: For the management, prophylaxis or treatment of anginal attacks.

Final classification of the less-than-effective indication requires further investigation.

**CONTRAINDICATIONS:**
Acute or recent myocardial infarction, severe anemia, closed-angle glaucoma, postural hypotension, increased intracranial pressure and idiosyncrasy to the drug.

**WARNINGS:**
Capsules must be swallowed. FOR ORAL, NOT SUBLINGUAL USE. Nitrostat SR Capsules are not intended for immediate relief of anginal attacks.

**PRECAUTIONS:**
Intraocular pressure may be increased; therefore, caution is required in administering to patients with glaucoma. Tolerance to this drug and cross-tolerance to other organic nitrites and nitrates may occur. If blurring of vision, dryness of mouth or lack of benefit occurs, the drug should be discontinued.

**ADVERSE REACTIONS:**
Severe and persistent headaches, cutaneous flushing, dizziness and weakness. Occasionally, drug rash or exfoliative dermatitis, and nausea and vomiting may occur; these responses may disappear with a decrease in dosage. Adverse effects are enhanced by ingestion of alcohol, which appears to increase absorption from the gastrointestinal tract.

**DOSAGE AND ADMINISTRATION:**
Administer the smallest effective dose 2 or 3 times daily, at 8- to 12-hour intervals, unless clinical response suggests a different regimen. Discontinue if not effective. 0883G010

### CONGENITAL HEART DISEASE

**237 Fetal Echocardiography. A Tool for Evaluation of In Utero Cardiac Arrhythmias and Monitoring of In Utero Therapy: Analysis of 71 Patients**

CHARLES S. KLEINMAN, RICHARD L. DONNERSTEIN, C. CARL JAFFE, GREGGORY R. DeVORE, ELLEN M. WEINSTEIN, DIANA C. LYNCH, NORMAN S. TALNER, RICHARD L. BERKOWITZ, and JOHN C. HOBBINS

Fetal echocardiographic studies were performed on 71 patients who had been referred for evaluation of cardiac rhythm disturbances at 24 to 40 weeks' gestation. After 2-dimensional echocardiographic study of cardiac structure, M-mode echocardiograms were analyzed for measurement of cardiac rate, atrioventricular contraction sequence, atrioventricular valve motion, and duration of postectopic pauses. Arrhythmias were diagnosed in 59 cases. In 34 patients with isolated ectopic beats, the arrhythmia resolved during later pregnancy (26) or within the first 5 days of life (8). Fourteen patients with mild sinus bradycardia (6) or frequent sinus pauses (8) had resolution of the arrhythmia during pregnancy. Sustained arrhythmias were noted in 11 patients. Fatalities occurred when there was associated fetal congestive heart failure (hydrops fetalis) or structural heart disease, or both. M-mode echocardiography diagnosed supraventricular tachycardia in 3 fetuses. The echocardiogram was used thereafter for monitoring of transplacental digoxin therapy.

**244 Assessment of Ventricular Size and Function in Congenitally Corrected Transposition of the Great Arteries**

THOMAS P. GRAHAM, Jr., MARK D. PARRISH, ROBERT J. BOUCEK, Jr., ROBERT C. BOERTH, JAMES A. BREITWESER, SANDRA THOMPSON, ROSE M. ROBERTSON, JOHN R. MORGAN, and GOTTLIEB C. FRIESINGER

Quantitative angiography was performed in 19 patients with congenitally corrected transposition of the great arteries to assess right and left ventricular size and function. Both systemic (anatomically right) end-diastolic volume and pulmonary (anatomically left) end-diastolic volumes were within normal limits in a majority of the patients. Pulmonary ventricular ejection fraction was also normal in most patients. Systemic ventricular ejection fraction was normal in a majority of patients aged $<10$ years, but 2 of 5 patients aged $>17$ years had low systemic ejection fractions, and an additional patient had a value at the lower limit of normal. After childhood, systemic ventricular dysfunction is not uncommon and may reflect the inability of the anatomic right ventricle to function as the systemic pumping chamber over a normal lifetime in a majority of patients with congenitally corrected transposition of the great arteries.

**252 Quantitation of Aortic and Mitral Regurgitation in the Pediatric Population: Evaluation by Radionuclide Angiocardiography**

ROGER A. HURWITZ, SALVADOR TREVES, MICHAEL FREED, DONALD A. GIROD, and RANDALL L. CALDWELL

Aortic or mitral regurgitation, or both, were estimated by determining the ratio of left to right ventricular stroke volume, obtained during equilibrium ventriculography. The radionuclide measurement was compared with the results of cineangiography, with good correlation between both studies in 47 of 48 patients. Radionuclide stroke volume ratio was used to classify severity: The group with equivocal regurgitation differed from the group with mild regurgitation ($p < 0.02$); patients with mild regurgitation differed from those with moderate regurgitation ($p < 0.001$); and those with moderate regurgitation differed from those with severe regurgitation ($p < 0.01$). The results of this study demonstrate that a stroke volume ratio $>2.0$ is compatible with moderately severe regurgitation and that a ratio $>3.0$ suggests the presence of severe regurgitation.

256 **Supraventricular Aortic Stenosis. A 20-Year Clinical Perspective and Experience With Patch Aortoplasty**

GREG FLAKER, DOUGLAS TESKE, JAMES KILMAN, DON HOSIER, and CHARLES WOOLEY

Supraventricular aortic stenosis has a wide range of clinical and morphologic expression, which influences the results of corrective surgery. Sixteen patients with supraventricular aortic stenosis underwent patch aortoplasty. At surgery, portions of the aortic valve cusps were frequently attached to supraventricular tissue. This "cusp tuck" resulted in distinctive angiographic features pre- and postoperatively. Of the 8 patients who underwent postoperative cardiac catheterization, all had a reduction in gradient between the left ventricle and the ascending aorta. Several patients had persistent gradients at the aortic valve level, which represented persistent attachment of aortic valve tissue to residual supraventricular tissue. Consequently, these morphologic features need to be recognized in order to plan an effective surgical approach.

261 **Radionuclide Stroke Count Ratios for Assessment of Right and Left Ventricular Volume Overload in Children**

MARK D. PARRISH, THOMAS P. GRAHAM, Jr., MARK L. BORN, JEROME P. JONES, ROBERT J. BOUCEK, Jr., MICHAEL ARTMAN, and C. LEON PARTAIN

A cineangiographic validation of the radionuclide determination of stroke count ratios in children for assessment of right and left ventricular volume overload is reported. Radionuclide stroke count ratios were determined in 60 children (aged 0.5 to 19 years, mean 11). Based on the diagnoses, these patients were divided into 3 groups: (1) normal (stroke count ratio 1.04 $\pm$ 0.17), (2) left ventricular volume overload (stroke count ratio 2.43 $\pm$ 0.86), and (3) right ventricular volume overload (stroke count ratio 0.44 $\pm$ 0.17). The radionuclide stroke count ratio clearly differentiated these groups ($p < .05$). In 22 of our 60 patients, radionuclide stroke count ratios were compared with cineangiographic stroke volume ratios, disclosing a correlation coefficient of 0.88. It is concluded that radionuclide ventriculography is an excellent tool for the qualitative and quantitative assessment of valvular regurgitation in children.

265 **Pulmonary Vascular Disease in Secundum Atrial Septal Defect in Childhood**

SHEILA G. HAWORTH

Pulmonary vascular structure was analysed in biopsy or autopsy tissue from the lungs of 10 patients with a secundum atrial septal defect (ASD) whom pulmonary hypertension had developed. Four patients were aged $\leq$6 months, 5 were aged 2 to 9 years, and 1 was 21 years old. Four infants presented in cardiac failure, all had a marked increase in pulmonary arterial smooth muscle, and only 1 infant survived surgery. Of the 5 older children, 3 had severe pulmonary vascular disease, similar to that seen in adults with hypertensive ASD, and only 2 underwent successful surgery. In 1 child and in the 1 adult, the severity of the pulmonary vascular disease precluded surgery. The ASD was closed in 8 patients, but only 3 children survived.

273 **Clinical Follow-Up Study of Paroxysmal Supraventricular Tachyarrhythmias After Operative Repair of a Secundum Type Septal Defect in Adults**

ROBERT O. BRANDENBURG, Jr., DAVID R. HOLMES, Jr., ROBERT O. BRANDENBURG, and DWIGHT C. McGOON

Paroxysmal supraventricular tachyarrhythmias are relatively common and may be the presenting symptom in adult patients with isolated atrial septal defects. The clinical course of these arrhythmias after surgical repair is unknown. Of 188 patients aged $\geq$44 years with isolated atrial septal defects, 27 (14%) had paroxysmal atrial tachyarrhythmias before operation: 16 with paroxysmal atrial fibrillation, 2 with paroxysmal atrial flutter, and 9 with paroxysmal supraventricular tachycardia. After operative repair, a mean follow-up of 12 years (range 1.5 to 25) was available. The outcome was dependent on the specific type of arrhythmia. Of the 18 patients with paroxysmal atrial flutter or fibrillation, 15 had sustained atrial fibrillation at follow-up, whereas of the 9 patients with preoperative paroxysmal supraventricular tachycardia, 5 had no further episodes at follow-up and 4 had a pronounced decrease in the frequency of paroxysmal arrhythmia.

Continued on Page A19

**Indications:** Premature atrial and ventricular contractions, aproxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, paroxysmal ventricular tachycardia when not associated with complete heartblock, maintenance therapy after electrical conversion of atrial fibrillation and/or flutter.

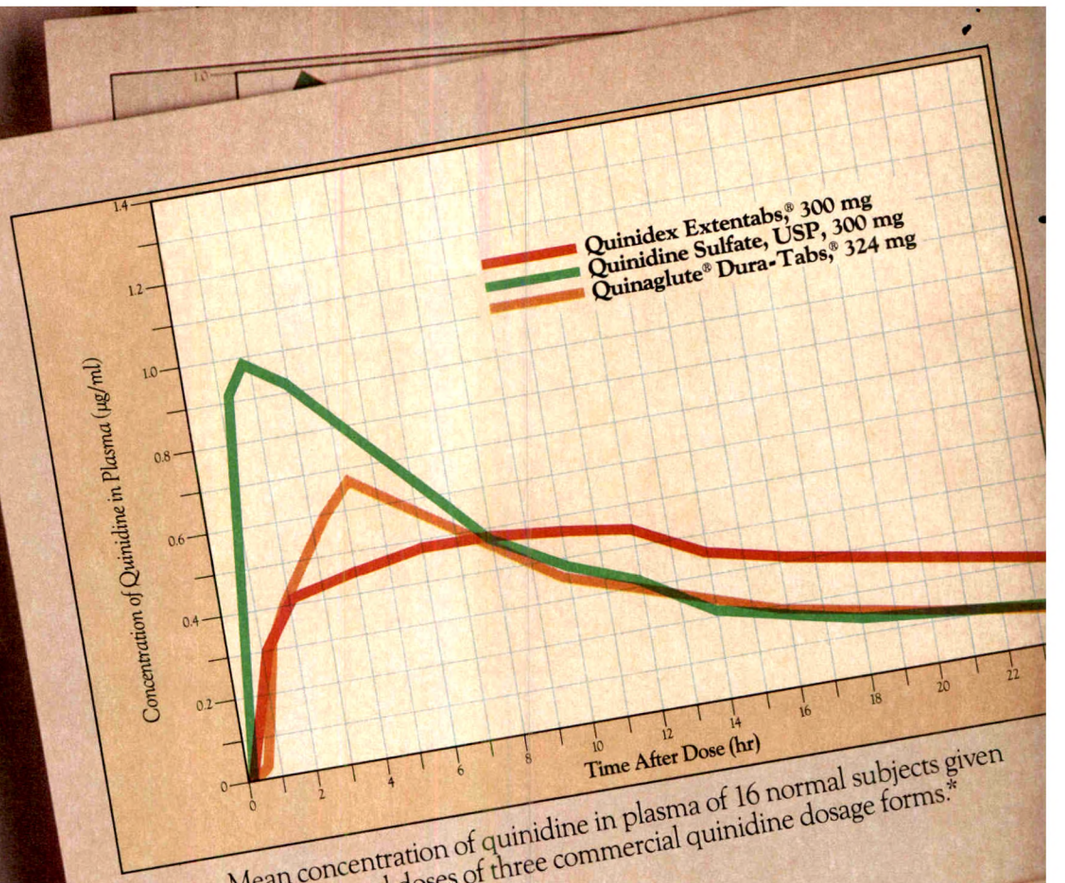
**Contraindications:** Intraventricular conduction defects. A-V block. Idiosyncrasy or hypersensitivity.

Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine.

**Warning:** In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio and resulting in extremely rapid ventricular rate.

**Precautions:** All the precautions applying to regular quinidine therapy apply to the Extentab form. Use with care in patients with severe congestive failure, renal insufficiency or with digitalis intoxication.

Patients should be carefully observed for signs of toxicity: e.g., (1) allergy or idiosyncrasy, such as febrile reactions, skin eruptions, and thrombocytopenia (extremely rare); (2) "cinchonism," such as tinnitus, blurred vision, dizziness, light-headedness, and tremor; (3) G.I. symptoms (nausea, vomiting, diarrhea, and colic); (4) cardiotoxic effects such as ventricular extrasystoles occurring at the rate of one or more every 6 normal beats, an increase of the QRS complex of 50% or more, a complete A-V block, or ventricular tachycardia.



NOTE: The development of "cinchonism" is not usually sufficient reason for terminating quinidine therapy. G.I. symptoms can also be minimized by giving the drug with food.

**Adverse Reactions:** Cases of quinidine-induced hypoprothrombinemic hemorrhage in patients on chronic anticoagulant drug therapy have been reported.

**Dosage:** Two Quinidex Extentabs every 8 to 12 hours.

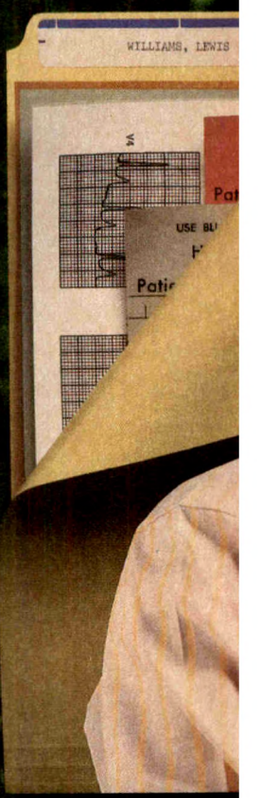
**How Supplied:** White sugar-coated Extentabs in bottles of 100 (NDC 0031-6649-63) and 250 (NDC 0031-6649-67) and Dis-co® Unit Dose Packs of 100 (NDC 0031-6649-64).

Rev. Dec. 1981

Mean concentration of quinidine in plasma of 16 normal subjects given single oral doses of three commercial quinidine dosage forms.*

# Consider The Evidence For Quinidex (Quinidine Sulfate, USP), 300 mg Extentabs®

- The convenience of b.i.d. dosage*
- Up to 12 hours of smooth, sustained release
- Relative bioavailability equal to Quinidine Sulfate Tablets, USP
- Contains 48 mg more active quinidine than the leading gluconate product



*Some patients may require a t.i.d. dosage schedule.

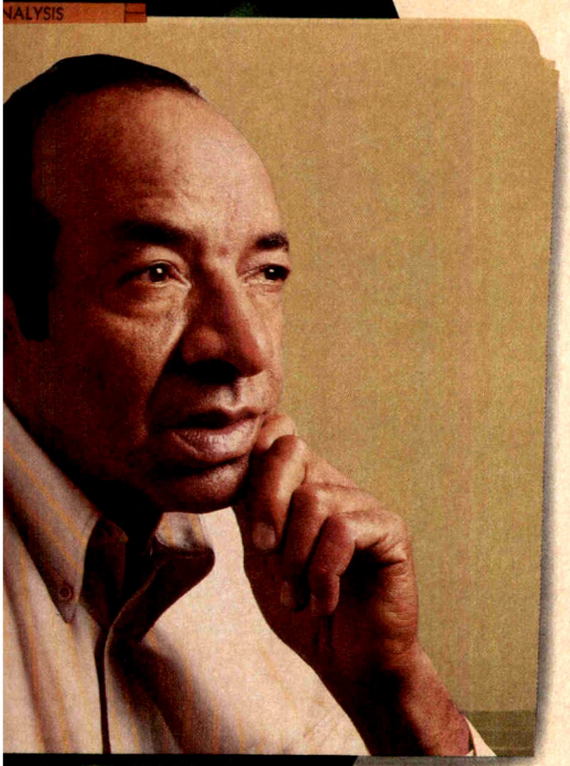
# LOOKING BENEATH THE SURFACE...



## may reveal the cause of his hypertension...

In their study of the humoral mechanisms involved in hypertension, researchers are focusing not only on the kidneys and adrenal glands but on other glandular bodies as well.

Recently, a new aldosterone-stimulating factor (ASF) has been isolated from normal human urine.* Through immunofluorescence, ASF—a glycoprotein with a number of similarities to ACTH and angiotensin II—has been traced to the pituitary gland. By helping to raise plasma levels of aldosterone, which in turn leads to increased renal sodium retention, ASF presumably contributes to hypertension. The importance of its role must still be determined—and eventually will be, as researchers continue to look "beneath the surface."

## as well as the cause of his excessive anxiety

When the hypertensive patient also has anxiety which may cause him to resist, or even ignore, his medical regimen, discreet probing often provides sufficient information about possible underlying causes to help you deal with the situation. At times, however, neither counseling nor reassurance seems to work. The patient remains tense, apprehensive and—perhaps most damaging of all—noncompliant.

In such cases, adjunctive Valium (diazepam/Roche) can be distinctly helpful. Valium works promptly and dependably to relieve the excessive anxiety that patients may have because of their concern over their organic illnesses. Typically, initial calming occurs within hours—more sustained, decisive relief of anxiety symptoms in just a few days. With his intense anxiety under control, the hypertensive patient may be better able to cope with his problems and to tolerate the demands of his treatment program.

Another important advantage: Valium has been used with most primary cardiac medications, including cardiac glycosides, diuretics and vasodilators. Side effects more serious than drowsiness, fatigue and ataxia are rare and seldom severe. Patients should, of course, be cautioned against drinking alcoholic beverages or driving while taking Valium. Periodic reassessment of the need for psychotropic medication is also recommended.

# VALIUM® (IV)

## diazepam/Roche

2-mg, 5-mg, 10-mg scored tablets

## A primary choice for anxiety associated with hypertension

Please see summary of product information on the next page.

ROCHE®

# VALIUM® (IV)
## diazepam/Roche

**Before prescribing, please consult complete product information, a summary of which follows:**
**Indications:** Management of anxiety disorders, or short-term relief of symptoms of anxiety. Anxiety or tension associated with the stress of everyday life usually does not require treatment with an anxiolytic. Symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).
The effectiveness of Valium in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.
**Contraindicated:** Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.
**Warnings:** Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms similar to those with barbiturates and alcohol have been observed with abrupt discontinuation, usually limited to extended use and excessive doses. Infrequently, milder withdrawal symptoms have been reported following abrupt discontinuation of benzodiazepines after continuous use, generally at higher therapeutic levels, for at least several months. After extended therapy, gradually taper dosage. Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.
***Usage in Pregnancy:*** **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**
**Precautions:** If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.
The clearance of Valium and certain other benzodiazepines can be delayed in association with Tagamet (cimetidine) administration. The clinical significance of this is unclear.
**Side Effects:** Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.
**Dosage:** Individualize for maximum beneficial effect. *Adults:* Anxiety disorders, symptoms of anxiety, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).
**How Supplied:** For oral administration, Valium scored tablets—2 mg, white; 5 mg, yellow; 10 mg, blue—bottles of 100* and 500;* Prescription Paks of 50, available in trays of 10* Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25,† and in boxes containing 10 strips of 10.†

## What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

## CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

***"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."*** Philip Reichert, M.D. New York State Journal of Medicine, September, 1981

***"...recommend...to any reader interested in the literature of cardiology."*** Irwin R. Callen, M.D. JAMA, November, 1981

**SPECIAL DISCOUNT OFFER**

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

☐ **YES,** please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

**277 Epicardial and Endocardial Activation in Patients With Endocardial Cushion Defect**

ROBERT M. CAMPBELL, MACDONALD DICK II, PAUL HEES, and DOUGLAS M. BEHRENDT

Examination of epicardial and left ventricular endocardial activation in 5 patients with endocardial cushion defect during surgical repair revealed an abnormal pattern of activation. Epicardial activation began at the diaphragmatic left ventricle surface and spread anterolaterally along the left ventricle, merged with right ventricle wave fronts, and then ended along the right ventricle anterior atrioventricular groove and outflow tract. Left ventricle endocardial activation also occurred earliest at the diaphramatic left ventricle segment with subsequent activation recorded laterally and anteriorly. This study demonstrates correlation between the pattern of left ventricle epicardial and endocardial activation, which is in accord with the known posteroinferior displacement of the specialized atrioventricular conduction system in patients with endocardial cushion defect.

**282 Atypical Fallot's Tetralogy With Doubly Committed Subarterial Ventricular Septal Defect. Diagnostic Value of 2-Dimensional Echocardiography**

HORACIO CAPELLI and JANE SOMERVILLE

Five patients with Fallot's tetralogy and doubly committed subarterial ventricular septal defect were correctly identified by 2-dimensional echocardiography before cardiac surgery. The short-axis view at the cardiac base from parasternal position best demonstrated the position of the defect in relation to the aortic, pulmonary, and tricuspid valves. By contrast, biplane angiography suggested the erroneous diagnosis of double outlet right ventricle with pulmonary valve stenosis in 3. This report emphasizes the importance of the preoperative diagnosis of this variant form which requires an outflow patch enlargement across the pulmonary ring although it frequently appears as a case of mild Fallot's tetralogy.

**286 Supraventricular Tachycardia in Infants: Use of the "Diving Reflex"**

VELIO SPERANDEO, DANIELE PIERI, PASQUALE PALAZZOLO, MARIO DONZELLI, and GIUSEPPE SPATARO

The effectiveness of the "diving reflex" in treating paroxysmal supraventricular tachycardia in 10 infants aged <6 months is demonstrated. The authors encountered no complications (rhythm disturbances), even when the maneuver was performed in patients who were receiving digitalis. The water temperature should be 5°C and the total time of facial immersion 6 to 7 seconds. We felt that the diving reflex must be considered as the first therapeutic approach in infants aged <6 months with paroxysmal supraventricular tachycardia.

**288 Impact of 2-Dimensional Echocardiography on the Management of Distressed Newborns in Whom Cardiac Disease Is Suspected**

MARY J. RICE, JAMES B. SEWARD, DONALD J. HAGLER, DOUGLAS D. MAIR, ROBERT H. FELDT, FRANCISCO J. PUGA, GORDON K. DANIELSON, WILLIAM D. EDWARDS, and ABDUL J. TAJIK

Forty consecutive sick newborns presenting with probable congenital heart disease were reviewed to determine the impact of 2-dimensional echocardiography in their management. Two-dimensional echocardiography correctly identified the major cardiac malformation in all cases. Only 40% of patients with congenital heart disease required cardiac catheterization in the neonatal period, and 43% of these procedures were primarily therapeutic (that is, balloon atrial septostomy). Forty-four percent of the patients treated surgically went directly to operation without preoperative catheterization. Two-dimensional echocardiography permits accurate noninvasive anatomic diagnosis of congenital heart disease in the newborn. Two-dimensional echocardiography thus expedites clinical management and reduces the need for cardiac catheterization.

**293 Rest and Exercise Ventricular Function in Adults With Congenital Ventricular Septal Defects**

GEORGE JABLONSKY, J. DAVID HILTON, PETER P. LIU, JOHN E. MORCH, MAURICE N. DRUCK, BEN-ZION BAR-SHLOMO, and PETER R. McLAUGHLIN, *With the technical assistance of* KATHY M. WINTER

Rest and exercise right and left ventricular function were compared in 19 normal control subjects and 34 patients with ventricular septal defect using gated radionuclide angiography. The patients were classified into 3 groups: (1) those with shunts closed at an early age; (2) patients with Eisenmenger complex; and (3) those with

**Continued on Page A20**

persistent small uncorrected shunts. All study patients failed to have an increase in ejection fraction in both ventricles on exercise as compared with the control subjects. It is concluded that (1) surgical correction failed to normalize ventricular function in patients with ventricular septal defect, (2) patients with Eisenmenger complex and abnormal resting left and right ventricular function, and (3) even patients with small shunts had an abnormal response to exercise, raising the possibility that chronic ventricular volume overload, even to a small degree, may be detrimental to ventricular function.

**299 Prognosis of Symptomatic Coarctation of the Aorta in Infancy**

PETER S. HESSLEIN, HOWARD P. GUTGESELL, and DAN G. McNAMARA

Medical and surgical advances have improved the outlook for infants with symptomatic coarctation of the aorta. In order to help predict the clinical course of individual patients and aid in individualizing their treatment, a 10-year experience with this condition was reviewed. Of 97 infants with symptomatic coarctation, 10 had isolated defects. In these patients, medical treatment was successful and surgical intervention could be postponed to allow for growth. The 87 other patients with associated cardiac defects were generally sicker at presentation and required earlier operation. Eleven of these died before surgical correction, 10 died at the time of repair, and 13 died later. The overall survival rate after 8 years was 62%, with most deaths occurring in the first 6 months of life. Late surgical results are flawed by a 32% rate of residual coarctation. Late postoperative hypertension is uncommon, and usually attributable to a residual coarctation.

**304 Instructions to Authors**

**VALVULAR HEART DISEASE**

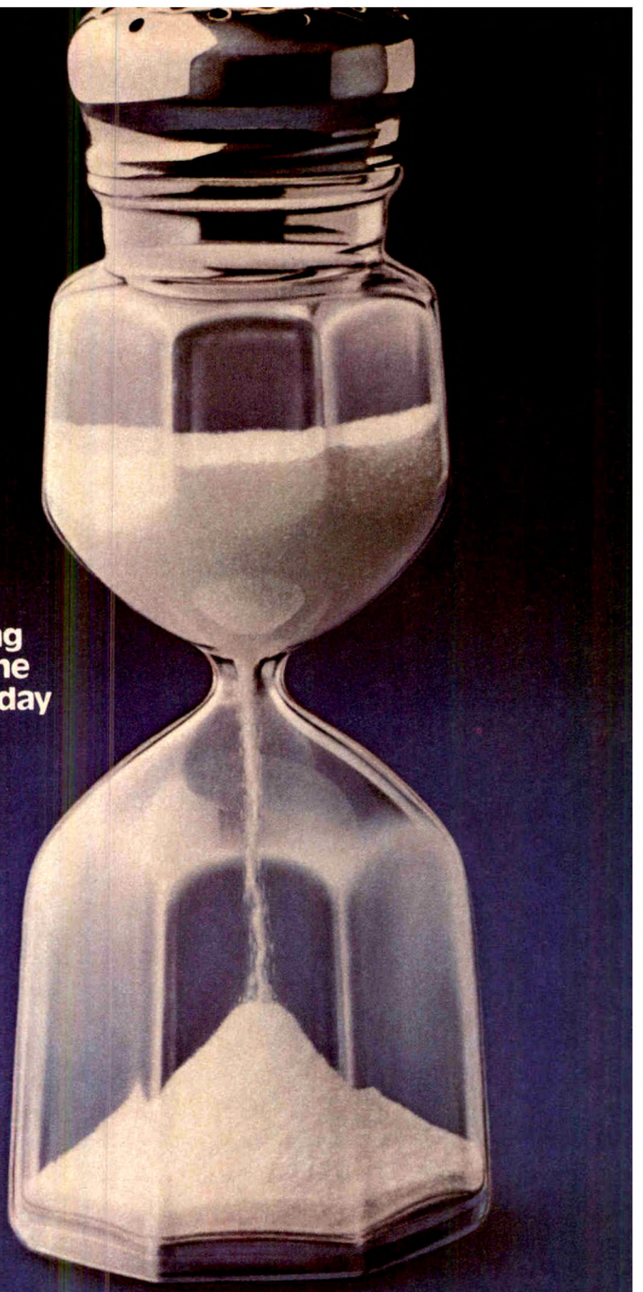
**305 Equilibrium Radionuclide Gated Angiography in Patients With Tricuspid Regurgitation**

BRUCE HANDLER, DAN G. PAVEL, RAYMOND PIETRAS, STEVEN SWIRYN, ERNEST BYROM, WILFRED LAM, and KENNETH M. ROSEN

Equilibrium gated radionuclide angiography was performed in 2 control groups (15 patients with no organic heart disease and 24 patients with organic heart disease but without right- or left-sided valvular regurgitation) and in 9 patients with clinical tricuspid regurgitation. The regurgitant index was significantly lower in the tricuspid regurgitation group than in either control group. A hepatic expansion fraction using time-activity variation over the liver was significantly higher in the tricuspid insufficiency group than in either control group. Fourier analysis was used to generate amplitude and phase images. All patients in the tricuspid insufficiency group had $>100$ pixels over an area corresponding to the liver on the amplitude image. These pixels were of phase comparable to that of the right atrium and approximately 180° out of phase with the right ventricle. In contrast, no patient in the 2 control groups had any pixels in an area corresponding to the liver. In conclusion, patients with tricuspid regurgitation were characterized on equilibrium gated angiography by an abnormally low regurgitant index, reflecting increased right ventricular stroke volume, increased hepatic expansion fraction, and increased amplitude of count variation over the liver in phase with the right atrium.

**311 The Apex Impulse in Mitral Stenosis: Graphic Explanation of the Palpable Movements at the Cardiac Apex**

JON FLOYD, PARK W. WILLIS IV, and ERNEST CRAIGE



To analyze the complex palpable movements at the cardiac apex in mitral stenosis, the noninvasive graphic records of 39 patients were studied retrospectively. Each patient had predominant mitral stenosis confirmed by cardiac catheterization. The simultaneously recorded apex- and phonocardiograms showed that a notch on the upstroke of the apex impulse, coincident with the first heart sound, occurred in 18 cases (47%). The notch ratio or vertical distance from the onset of the apical impulse to the notch was calculated as a percentage of the total upstroke. Statistical analysis showed a significant relation ($r = 0.61$, $p < 0.01$) between the notch ratio and the mean mitral diastolic gradient. This graphic measurement of the extent of delay of the first heart sound with respect to the onset of the apical thrust can provide a rough measure of the severity of valvular obstruction.

When sodium excretion is important in the management of hypertension...

# Hygroton® 25 mg one a day (chlorthalidone USP)

## no other diuretic blocks sodium retention longer

**Hygroton®**
(chlorthalidone USP)

**BRIEF SUMMARY**

**Indications:** Hypertension, adjunctive therapy in edema. **Contraindications:** Anuria, hypersensitivity to chlorthalidone or other sulfonamide-derived drugs. **Warnings:** Should be used with caution in severe renal disease, impaired hepatic function or progressive liver disease. May add to or potentiate the action of other antihypertensive drugs. Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma. There is a possibility of exacerbation or activation of systemic lupus erythematosus with thiazides, which are related to chlorthalidone. This has not been reported with chlorthalidone. Thiazides cross the placental barrier and appear in cord blood. Use in pregnant women requires that the anticipated benefits of the drug be weighed against possible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult. In nursing mothers, thiazides cross the placental barrier and appear in breast milk. If use of the drug is essential, the patient should stop nursing. **Precautions:** Periodic determination of serum electrolytes to detect possible electrolyte imbalance should be performed at appropriate intervals. All patients receiving chlorthalidone should be observed for clinical signs of fluid or electrolyte imbalance; namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations [illegible] when the patient is receiving excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with chlorthalidone as with any other potent diuretic, especially with brisk diuresis, when severe cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially with reference to myocardial activity. Any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather. Hyperuricemia may occur or gout be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged and latent diabetes mellitus may become manifest. Chlorthalidone and related drugs may increase the responsiveness to tubocurarine. The antihypertensive effects of the drug may be enhanced in the postsympathectomy patient. Chlorthalidone and related drugs may decrease arterial responsiveness to norepinephrine. If progressive renal impairment becomes evident, as indicated by a rising nonprotein nitrogen or blood urea nitrogen, a careful reappraisal of therapy is necessary with consideration given to withholding or discontinuing diuretic [illegible] serum PBI levels without signs of thyroid disturbance. **Adverse Reactions:** Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis; dizziness, vertigo, paresthesias, headache, xanthopsia; leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia; purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), Lyell's syndrome (toxic epidermal necrolysis). Orthostatic hypotension may occur and may be aggravated by alcohol, barbiturates or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, impotence. Whenever adverse reactions are moderate or severe, chlorthalidone dosage should be reduced or therapy withdrawn. **Usual Dose:** One tablet daily. **How Supplied:** Tablets—100 mg. (white, scored), 50 mg. (aqua) in bottles of 100, 1000 and 5000; 25 mg. (peach) in bottles of 100 and 1000; unit-dose blister packs, boxes of 100 (10 x 10 strips).

**315 Coronary Vascular Reserve in Left Ventricular Hypertrophy Secondary to Chronic Aortic Regurgitation**

AUGUSTO D. PICHARD, HARRY SMITH, JAMES HOLT, JOSE MELLER, and RICHARD GORLIN

Coronary vascular reserve in 11 patients with left ventricular hypertrophy secondary to chronic aortic regurgitation was analyzed by looking at the hyperemic reaction induced in the coronary flow by the selective coronary injection of contrast agent. Compared with a control group, patients with hypertrophy had increased coronary flow at rest and decreased coronary reserve. This decrease is proportional to the increase in left ventricular mass; left ventricular wall thickness and not left ventricular volume is the critical component of left ventricular mass related to the decreased coronary reserve.

**321 Regurgitation of Prosthetic Heart Valves: Dependence on Heart Rate and Cardiac Output**

KEVIN C. DELLSPERGER, DAVID W. WIETING, DEBRA A. BAEHR, ROBERT J. BARD, JEAN-PIERRE BRUGGER, and EARL C. HARRISION

Prosthetic heart valves exhibit closure and leakage backflow; however, no well-controlled study to evaluate the influence of factors such as cardiac output and heart rate on backflow have been reported to date. Four clinically used prosthetic aortic valves (size 27 mm)—St. Jude Medical, Björk-Shiley Spherical Disc, Björk-Shiley Convexo Concave, and Start-Edwards model 1260—were studied in the aortic chamber of a pulse duplication system at heart rates of 50, 80, 110, and 140 beats/min, cardiac outputs of 2, 4, 6, and 8 liters/min, and mean aortic pressure of 100 mm Hg. Percent regurgitation varied directly with heart rate and inversely with cardiac output. Regurgitation associated with prosthetic heart valves may present a problem clinically, particularly under conditions of low cardiac output and tachycardia.

**MISCELLANEOUS TOPICS**

**329 Noninvasive Detection of Active Pericardial Bleeding Using Cardiac Blood Pool Scintigraphy**

TIMOTHY M. BATEMAN, RASHID MASSUMI, RICHARD J. GRAY, AURELIO CHAUX, MICHELE A. DeROBERTIS, DAVID E. BROWN, JACK M. MATLOFF, and DANIEL S. BERMAN

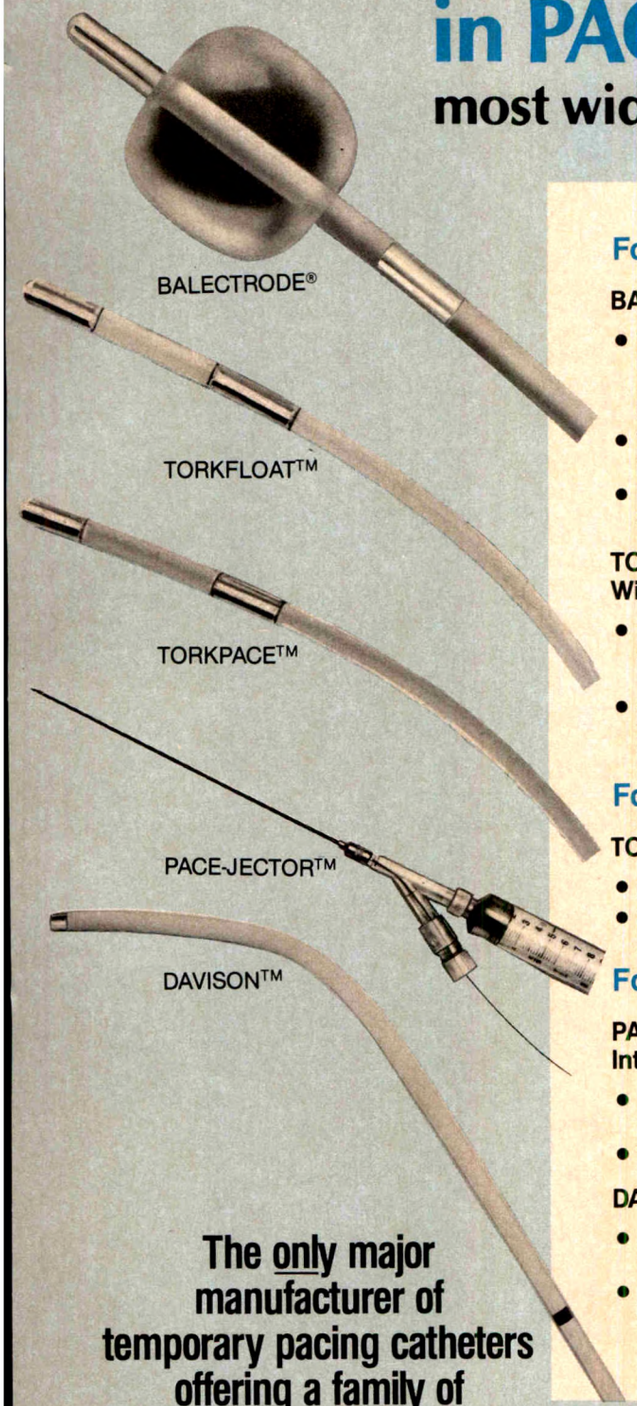
The diagnosis of active pericardial bleeding has traditionally depended upon an invasive documentation by needle aspiration, angiography, or direct inspection. Nuclear techniques that allow the localization of labeled erythrocytes may have considerable utility in the detection of active pericardial hemorrhage. In vitro technetium-99m labeled red blood cell scintigraphy performed in 2 patients before and again just after the development of hemopericardium revealed unique images in which acute pericardial bleeding was manifested by an additional blood pool adjacent to and surrounding the cardiac chambers. With appropriate attention to technical factors, such distinctive images should be highly specific for active bleeding into the pericardium.

**332 Assessment of the Cardiac Effects of Hemodialysis With Systolic Time Intervals and Echocardiography**

ABRAHAM BORNSTEIN, WILLIAM H. GAASCH, and JOHN HARRINGTON

Using externally recorded systolic time intervals and echocardiography, the acute effects of hemodialysis on left ventricular function were studied in 10 patients. The major hemodynamic change associated with dialysis was a decrease in stroke volume due to a decrease in preload. Dialysis was also associated with an increase in left ventricular contractility.

**336 Normal Left Atrial Function Determined by 2-Dimensional Echocardiography**



JACK GUTMAN, YIN SHI WANG, DENNIS WAHR, and NELSON B. SCHILLER

To obtain normal values for left atrial function noninvasively, the volumes of the left atrium and ventricle were calculated in each of 52 volunteer subjects by means of 2-dimensional echocardiography. A light pen digitizing and computation system, controlled by a microprocessor, was used to outline the left atrium and ventricle in orthogonal apical views. Then, to calculate end-systolic and end-diastolic atrial and ventricular volumes, a modified Simpson's rule formula was used. The mean (± standard deviation) end-systolic left atrial volume was 37 ± 11.7 ml or 21 ± 6.6 ml/m$^2$. The change in left atrial volume from end-systole to end-diastole was 24 ± 7.6 ml or 13.5 ± 4.3 ml/m$^2$, which represented 37 ± 12.9% of left ventricular stroke volume. The mean fractional emptying of the left atrium was 65 ± 8.9% and the conduit volume was 41 ± 14.0 ml or 23 ± 7.9 ml/m$^2$. These values are similar to those reported in studies which calculated left atrial function from contrast angiography.

# ELECATH®... Leading the way in PACING CATHETERS

## most widely used... widest selection

### For Placement *without* Fluoroscopy

**BALECTRODE® Balloon Flow-Directed Pacing Kit**

- The *only* major manufacturer of Balloon Flow-Directed pacing products to offer non-corroding *platinum* electrodes to assure optimal physiological response, and to prevent the migration effect seen in stainless steel electrodes.
- Two French sizes are available: 3 French (KBE1) and 5 French (KBE2) for various patient physiological requirements.
- Complete sterile kit, consisting of an introducer, shielded EKG adapter, and vented syringe for exact, accurate balloon inflation.

**TORKFLOAT™ Semi-Floating Pacing Kit With 1:1 Torque Response**

- The *only* major manufacturer of semi-floating pacing products to offer non-corroding *platinum* electrodes to assure optimal physiological response.
- Complete kit includes pacing catheter with centimeter markings, introducer and sterile shielded EKG adapter for artifact-free EKG tracing, for confirmation of placement.

### For Placement *with* Fluoroscopy

**TORKPACE™ Standard Pervenous Pacing Probes**

- *Platinum* electrodes to assure optimal physiological response.
- Hybrid inner core design provides a semi-flexible catheter tip for better flexibility for permanence of position and safety.

### For Emergency Pacing

**PACE-JECTOR™—The Unique Dual Purpose Pacing And Intracardiac Medication System (11-KPJ1)**

- Direct electrical stimulation and/or pharmacological manipulation of the unresponsive myocardium is immediately available.
- The pacing stylet is *pre-loaded* for simple intraventricular placement.

**DAVISON™—Emergency Transvenous Pacing Lead (11-KTFD)**

- Capture achieved as soon as the proximal electrode emerges from the introducer sheath.
- *Platinum* electrodes located 19cm apart assure conduction system stimulation regardless of catheter tip position in the ventricle.

**The only major manufacturer of temporary pacing catheters offering a family of non-corrosive platinum electrodes.**

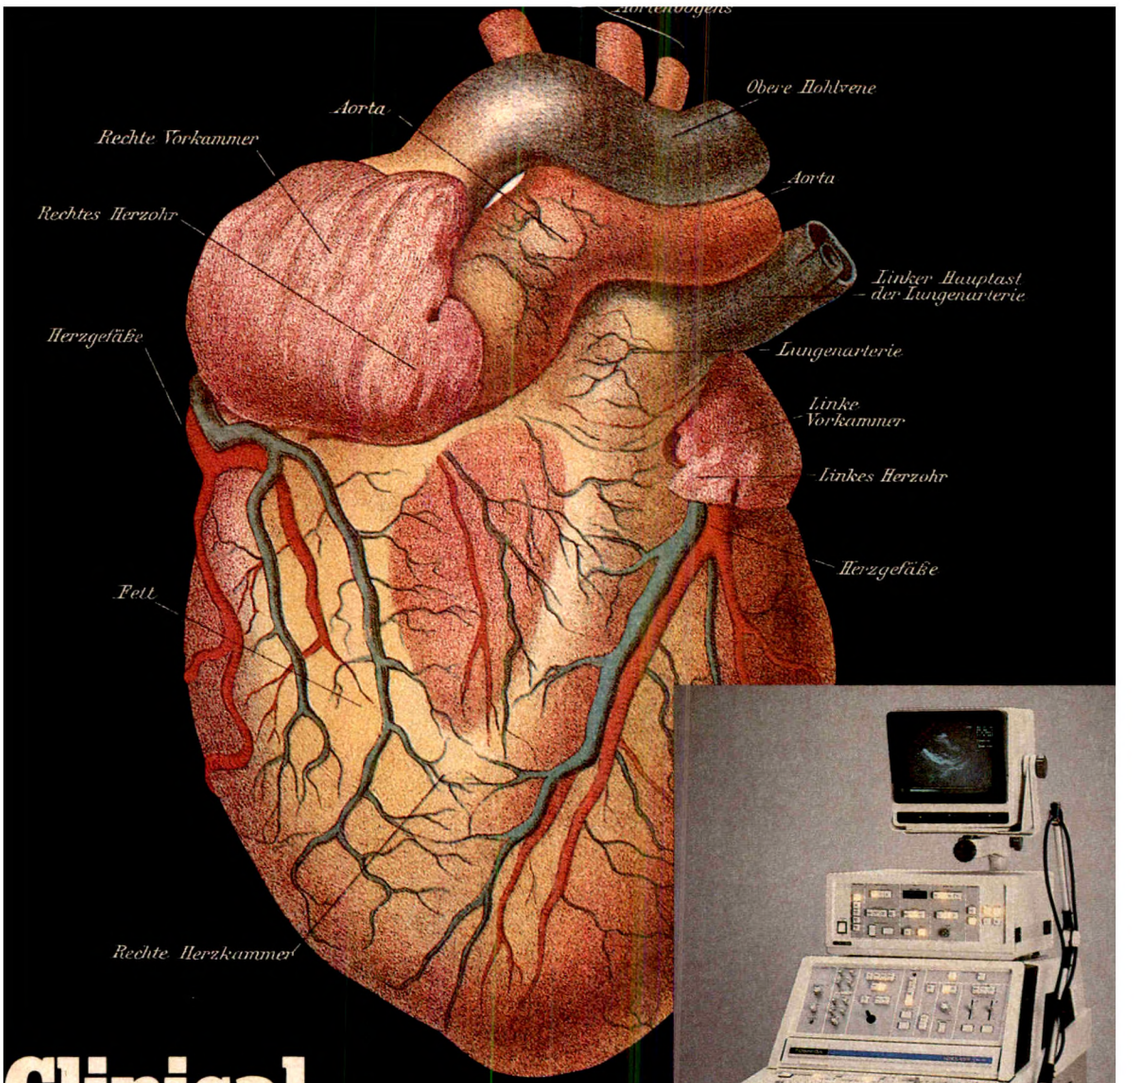
**341 Myocardial Function in Rocky Mountain Spotted Fever: Echocardiographic Assessment**

JOSÉ MARIN-GARCIA and FRED F. BARRETT

Rocky Mountain spotted fever is a serious infectious disease that continues to occur with increasing incidence in various areas of the United States. A high case-fatality ratio (7 to 11%) persists despite availability of adequate chemotherapeutic agents. Cardiac involvement may play an important role in the final outcome in some cases. Nine children with Rocky Mountain spotted fever underwent echocardiographic examination on admission to a children's hospital. Increased left ventricular dimension was found in 2 and abnormal left ventricle function indexes in 7. One patient died and diffuse myocarditis was seen at autopsy. Abnormal echocardiographic findings remained in 3 patients at follow-up (mean 10 months). Awareness of the cardiac involvement in Rocky Mountain spotted fever is important and close follow-up warranted.

**344 Mechanisms for Decreased Exercise Capacity After Bed Rest in Normal Middle-Aged Men**

JOSEPH HUNG, DANIELLE GOLDWATER, VICTOR A. CONVERTINO, JAMES H. McKILLOP, MICHAEL L. GORIS, and ROBERT F. DeBUSK



Echocardiographic and radionuclide studies in 12 healthy middle-aged men after 10 days of bed rest disclosed decreased left ventricular end-diastolic volume but increased exercise heart rate and left ventricular ejection fraction, so that peak oxygen uptake during supine effort did not decrease significantly after bed rest. These mechanisms were insufficient to compensate for the reduced cardiac volume in the upright position, and peak oxygen uptake during upright effort decreased significantly after bed rest. These results indicate that the major cause of reduced effort tolerance after prolonged bed rest in normal middle-aged men was orthostatistically induced cardiac underfilling, not physical deconditioning or left ventricular dysfunction.

**349 Cardiac Performance in Thyrotoxicosis: Analysis of 10 Untreated Patients**

ABDULMASSIH S. ISKANDRIAN, LESLIE ROSE, A-HAMID HAKKI, BERNARD L. SEGAL, and SALLY A. KANE

The purpose of this study was to define the cardiac performance at rest and during exercise in 10 patients with untreated thyrotoxicosis. Resting left ventricular function was normal in all patients, but the exercise ejection fraction response was abnormal in 3 of 10 patients. Thus, abnormal left ventricular reserve function during exercise can be detected in 30 percent of patients with untreated thyrotoxicosis.

# Clinical versatility redefined.

The TOSHIBA SSH-40A Cardiac Phased Array Sector Scanner brings new meaning to clinical versatility. The SSH-40A offers superb image quality, extensive computational capability, and the ability to perform a wide variety of examinations. It incorporates advanced technological developments such as: Automatic Electronic Focusing, the field's first Two Dimensional Gate Array Doppler, and a very powerful on-board computer. From neonates to adults, from standard views to special flow studies, from simple imaging to functional calculations, the new SSH-40A is truly a new generation in phased array.

You expect new innovations from TOSHIBA. We're the Total Imaging Company with over 12,000 ultrasound scanners in use throughout

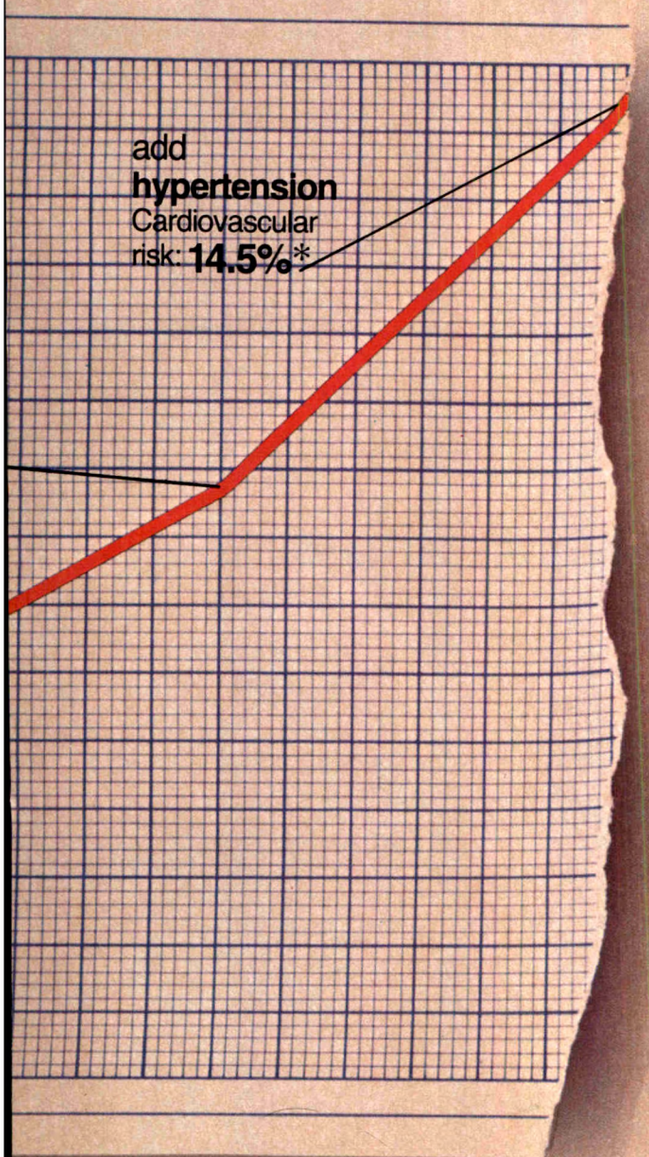
# In hypertensive patients:



Other risk factors in CHD are diabetes, obesity, lack of exercise, stress, heredity, sex, age, race.

*Percent equals chances in 100 of developing coronary heart disease within 6 years.

Adapted from *Coronary Risk Handbook:* Estimating risk of coronary heart disease in daily practice. 1973, American Heart Assoc., Inc.

# Consider the Risks

- When selecting antihypertensive therapy, clinical consideration should be given to the effects of the specific drug on coronary risk factors. Blood pressure control should be achieved without adversely affecting blood lipids.

## Minipress Effectively Controls Hypertension Without Adverse Effect on Blood Lipids†

- Minipress effectively treats hypertension. Patients have benefited from the effectiveness of Minipress in over 5 years of clinical use in this country.[1-5]

- Minipress has been shown not to have an adverse effect on blood lipids, according to The Oslo Study and other reports.[6-9] Because Minipress lowers high blood pressure and does not produce lipid changes which are potentially atherogenic, it provides your patient with a net reduction in risk.

†Minipress is not indicated for the treatment of hyperlipidemia.

*Please see Minipress brief summary on following page.*

# Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

© 1982, Pfizer Inc.

# Minipress® (prazosin HCl) Capsules 1mg 2mg 5mg

**B.I.D. Dosage Convenience**

**BRIEF SUMMARY**

**MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use***

**INDICATIONS:** MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.

**WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.**

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

***Usage in Pregnancy:*** Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

***Usage in Children:*** No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

**ADVERSE REACTIONS:** The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established.)

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus, alopecia, lichen planus.

Genitourinary: urinary frequency, incontinence, impotence, priapism.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

**DOSAGE AND ADMINISTRATION:** The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

***Initial Dose:*** 1 mg two or three times a day. (See Warnings.)

***Maintenance Dose:*** Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however, a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

***Use With Other Drugs:*** When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

**HOW SUPPLIED:** MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

# MYOCARDIAL REVASCULARIZATION

## MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

**The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.**

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

## Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

CONGENITAL HEART DISEASE

# Fetal Echocardiography

## A Tool for Evaluation of In Utero Cardiac Arrhythmias and Monitoring of In Utero Therapy: Analysis of 71 Patients

CHARLES S. KLEINMAN, MD, RICHARD L. DONNERSTEIN, MD, C. CARL JAFFE, MD, GREGGORY R. DeVORE, MD, ELLEN M. WEINSTEIN, MD, DIANA C. LYNCH, RN, NORMAN S. TALNER, MD, RICHARD L. BERKOWITZ, MD, and JOHN C. HOBBINS, MD

**Fetal echocardiographic studies were performed in 71 patients referred for evaluation of cardiac rhythm disturbances at 24 to 40 weeks' gestation. After 2-dimensional echocardiographic study of cardiac structure was performed, M-mode echocardiograms were analyzed for measurement of cardiac rate, atrioventricular contraction sequence, atrioventricular valve motion, and duration of postectopic pauses. Arrhythmias were diagnosed in 59 patients. In 34 patients with isolated ectopic beats, the arrhythmia resolved during later pregnancy in 26 or within the first 5 days of life in 8. Six patients had mild sinus bradycardia and 8 had frequent sinus pauses; all 14 had resolution of the arrhythmia during pregnancy. Sustained arrhythmias occurred in 11 patients. Deaths occurred when there was associated fetal congestive heart failure (hydrops fetalis), structural heart disease, or both. M-mode echocardiography diagnosed supraventricular tachycardia in 3 fetuses. The echocardiogram was used thereafter for monitoring transplacental digoxin therapy.**

Over the past few years, echocardiographic imaging techniques have been applied by several groups interested in the detection of structural heart disease in utero.[1–5] There have also been isolated reports of cardiac rhythm disturbances detected by these techniques. We previously reported experience in detecting congenital cardiac malformations in a prospective study of patients deemed at higher than normal risk for such abnormalities, and we also reported an initial experience with the diagnosis of in utero cardiac arrhythmias.[1,6–14] This report expands our discussion of the use of ultrasound for the diagnosis of fetal cardiac rhythm disturbances and the use of M-mode and real-time fetal echocardiography for monitoring in utero antiarrhythmic therapy as illustrated by our experience with 71 patients.

From the Departments of Pediatrics, Obstetrics and Gynecology, and Diagnostic Radiology, Yale University School of Medicine, New Haven, Connecticut. This study was supported in part by grants from the March of Dimes Birth Defects Foundation, White Plains, New York, and The Thrasher Research Fund, Salt Lake City, Utah. Manuscript received May 10, 1982; revised manuscript received July 6, 1982, accepted July 9, 1982.

Address for reprints: Charles S. Kleinman, MD, Division of Pediatric Cardiology, Yale University School of Medicine, PO Box 3333, New Haven, Connecticut 06510.

### Methods

Seventy-one patients at 21 to 40 weeks of gestation were referred by their obstetricians for evaluation of abnormal fetal cardiac rates or rhythms, or both. These included fetuses with regular heart rates >180 beats/min or <100 beats/min or those with irregular rhythms. Rhythmic variations of a regular rate, representing sinus arrhythmias, or transient accelerations or decelerations during labor of an otherwise regular rhythm, are considered normal. The normal fetal heart rate varies from 120 to 160 beats/min.[15,16]

Fetal echocardiography was performed after fetal position within the uterus, and the relation of the fetal heart to the maternal abdominal wall was determined using either an ATL

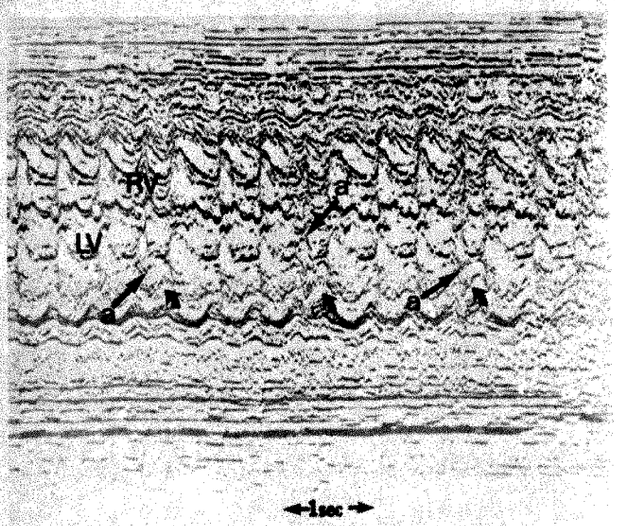

**FIGURE 1.** Supraventricular premature contractions demonstrated on an M-mode echocardiogram performed at the mid-ventricular level in a mid-trimester fetus. Three premature contractions are demonstrated. The mitral valve is seen within the left ventricular (LV) cavity. Presystolic atrial activity is reflected by the presence of A waves (**straight arrows**) of the mitral valve. These precede the premature ventricular responses which are represented by premature movement of the left ventricular posterior wall (**curved arrows**). RV = right ventricle.

Mark III, a Picker 80 CI, or a Diasonics CardioVue 100 2-dimensional cardiac sector-scanner with a 3.5 or 5.0 mHz transducer. After 2-dimensional echocardiographic analysis of fetal cardiac structure was performed and the rate and regularity of the cardiac rhythm were grossly evaluated in real-time, a simultaneous or sequential M-mode study, or both, were performed by stopping the motion of the mechanically swept transducer in the desired location. The 2-dimensional scan is indispensible for providing structural information regarding the heart and for defining the axis in which the M-mode study is performed. Two-dimensionally directed M-mode echocardiography, due to its rapid sampling rate and ability to obtain a hard copy of the tracing, demonstrating cardiac motion as a function of time, is well suited for evaluation of cardiac rhythm disturbances.[17] By allowing evaluation of atrioventricular contraction sequence, septal motion pattern, postectopic pauses, and atrioventricular valve motion, the site of origin of a premature contraction may be suggested. Premature supraventricular beats are usually preceded by demonstrable A waves before premature valve closure (Fig. 1), whereas in ventricular premature contractions the premature beats frequently precede atrial depolarization, therefore aborting mitral A waves during that cardiac cycle (Fig. 2). The postectopic pause may be suggestive (but not diagnostic) of the site of the origin of premature contractions (Fig. 3). In complete heart block, the atrioventricular dissociation may be demonstrated by examining atrioventricular valve motion which shows A waves which "march through" mitral valve closure points without a fixed relation between these events (Fig. 4).[1,13,14] The relation between atrial wall motion, atrioventricular valve motion, and ventricular wall response rate can be used to diagnose varying degrees of second-degree atrioventricular block (Fig. 5).

**TABLE I Fetal Arrhythmias in 58 Patients**

| Arrhythmia | Patients (n) |
|---|---|
| **Self-Limited** | |
| Supraventricular ectopic beats | 32 |
| Ventricular ectopic beats | 2 |
| Sinus bradycardia | 6 |
| Sinus pauses | 8 |
| Subtotal | 48 |
| **Sustained** | |
| Atrial flutter | 2 |
| Supraventricular tachycardia | 2 |
| Complex arrhythmia | 1 |
| Complete heart block | 2 |
| Supraventricular ectopic beats | 2 |
| Sinus bradycardia | 1 |
| Subtotal | 10 |

## Results

Satisfactory M-mode and real-time studies were obtained in all of the patients examined. A satisfactory M-mode study allowed accurate evaluation of fetal heart rate and the regularity of the cardiac rhythm. Fetal M-mode echocardiograms were compared to

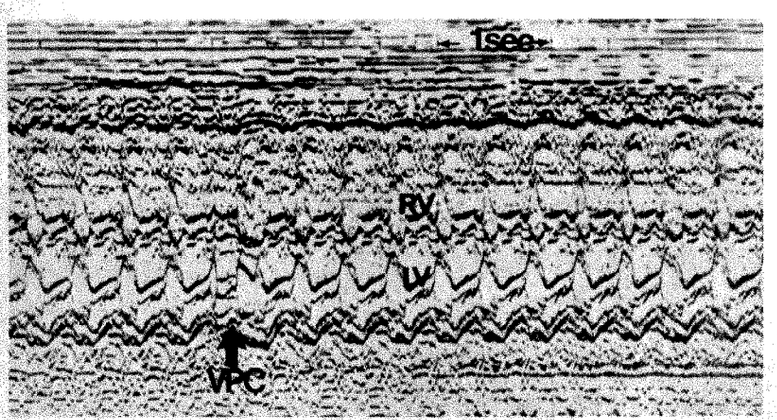

**FIGURE 2.** Ventricular premature contractions (VPC) seen on an M-mode echocardiogram performed at the mid-ventricular level in a mid-trimester fetus. The premature contraction is reflected by the presence of an early undulation of the left ventricular posterior wall (**bold arrow**). The mitral valve is seen within the left ventricular cavity. With this ventricular premature contraction, the premature beat preceded atrial depolarization, aborting mitral A-wave activity during that cardiac cycle. The postectopic pause is compensatory. LV = left ventricle; RV = right ventricle.

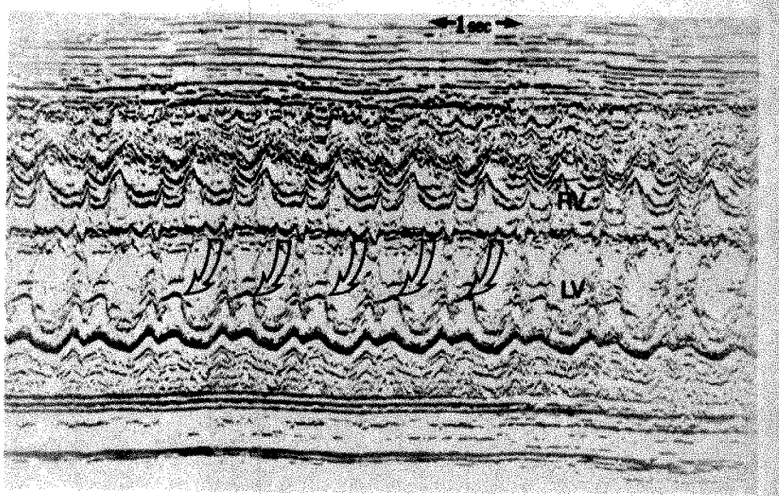

**FIGURE 3.** M-mode echocardiographic scan at the mid-ventricular level in the same patient depicted in Figure 1. At this time, the patient who had shown evidence of isolated supraventricular ectopy has developed atrial bigeminy. The atrial premature beats (**curved arrows**) appear coupled to the preceding normal beat. LV = left ventricle; RV = right ventricle.

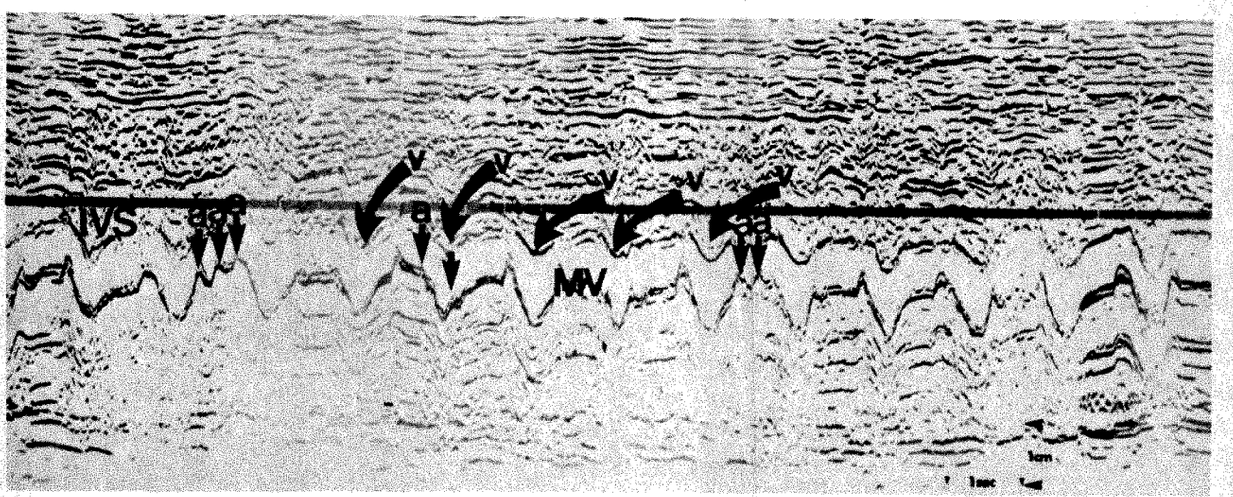

**FIGURE 4.** M-mode echocardiographic scan at the level of the left ventricle at 28 weeks' gestation. A slow and regular idioventricular rate of 45 to 50 beats/min is reflected in the undulations (v, **curved arrows**) of the interventricular septum (IVS). Atrial contractions (a, **straight arrows**) cause regular undulations of the mitral valve (MV) at a rate of approximately 120 to 130 beats/min. There are brief episodes of atrial flutter at a rate of 300 beats/min. The atrial activity bears no fixed relation to the idioventricular rhythm. This patient had complete heart block.

postnatal electrocardiograms in the patients who had arrhythmias persisting beyond delivery, thus confirming the arrhythmia interpretation in these cases. A satisfactory 2-dimensional scan allowed structural analysis of the 4 cardiac valves and the interventricular and interatrial septa. Fifty-nine of the 71 patients were documented to have rhythm disturbances at the time of the echocardiographic study. Of these 59 patients, 48 had isolated premature beats, sinus pauses, or periods of bradycardia (Table I). Thirty-two patients were thought to have supraventricular ectopy (Fig. 1) and 2 had isolated ventricular premature contractions (Fig. 2). Six fetuses had regular bradycardia with heart rates of 90 to 100 beats/min in the absence of uterine contractions, and 1 fetus had a bradycardia of 60 beats/min. Sustained arrhythmias were noted in 11 patients: 2 with complete heart block, 1 with complex supraventricular and ventricular arrhythmia, 2 with atrial flutter, 3 with supraventricular tachycardia, the 1 patient with severe sinus bradycardia, and 2 patients with isolated supraventricular ectopic beats.

All patients discussed herein were subsequently delivered. Twenty-five of the fetuses with isolated ectopic beats (including 1 with atrial bigeminy (Fig. 3) and 1 of the 2 thought to have ventricular ectopy) demonstrated resolution of the arrhythmia before delivery. Eight patients had isolated atrial premature contractions and 1 patient had isolated ventricular premature contractions that spontaneously resolved on Holter monitoring by the fifth day of life. Two patients continued to have isolated supraventricular ectopy on discharge from the nursery. One has had resolution of the arrhythmia on Holter monitoring at 6 months of age; 1 continues to have isolated junctional ectopic beats at age 6 months.

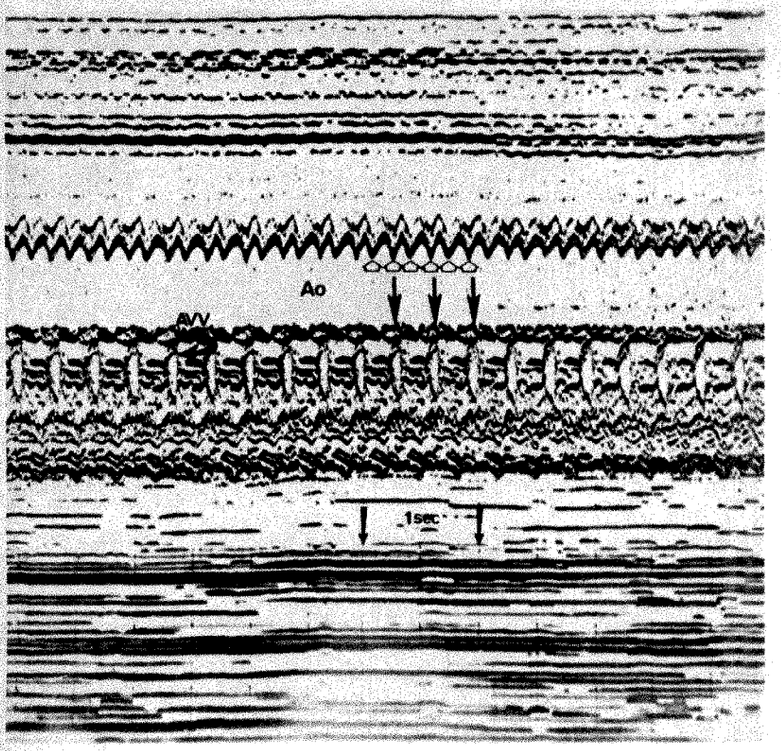

**FIGURE 5.** Atrial flutter with 2:1 atrioventricular block in a third-trimester fetus. The transducer beam was oriented from posterior to anterior in this fetus, who was oriented in an occiput anterior presentation. Rapid and regular atrial contractions are reflected on the posterior wall of the aorta (Ao, **open arrows**) at an atrial rate of 360 beats/min. The interventricular septum (**straight arrows**) and atrioventricular valve (AVV) respond to every other atrial contraction, resulting in a ventricular rate of approximately 180 beats/min. (The AVV is the tricuspid valve.)

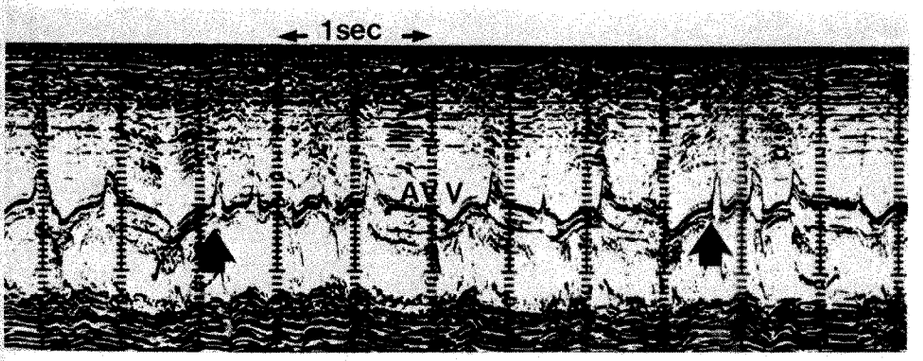

**FIGURE 6.** M-mode echocardiogram at the ventricular level in a third-trimester fetus. This fetus had been noted earlier in gestation to have isolated supraventricular premature contractions. On this scan, 2 self-limited episodes of supraventricular tachycardia are reflected in rapid undulations (**bold arrows**) of the atrioventricular valve (AVV). The first burst of tachycardia is of 5 beats' duration, the second burst of 3 beats' duration. This fetus developed a protracted episode of supraventricular tachycardia later in gestation.[2]

The arrhythmias of the 6 patients with mild bradycardia (90 to 100 beats/min) and the 8 patients with sinus pauses all resolved during gestation.

Table II summarizes the clinical information from our 11 patients with sustained fetal arrhythmias. In the first child found to have complete heart block (Patient 7) diagnosis was obtained by M-mode echocardiography at 28 weeks' gestation.[1] That child was followed throughout pregnancy and did well in the 3 years since birth, requiring no therapy for the persistent heart block. After diagnosis, a maternal history and serologic studies consistent with a diagnosis of systemic lupus erythematosus were documented.[19,20]

Several of the patients with sustained arrhythmias had associated nonimmune hydrops fetalis, structural heart disease, or both, as described in an earlier report from our laboratory.[2]

Fetal or immediate neonatal wastage was encountered when there was associated evidence of congenital cardiac malformation, severe hydrops fetalis, or both. This was the case in Patient 8, who was diagnosed as having complete heart block (Fig. 4) with associated isolated levocardia and congestive cardiac failure. Postmortem examination confirmed these diagnoses, in addition to polysplenia.[21]

Patient 6 had a chaotic rhythm with associated tetralogy of Fallot and polyhydramnios that was attributed to cardiomyopathy. This child died on the fifth day of life due to intractable ventricular arrhythmias.

Patient 1 was stillborn after the diagnosis of atrial flutter with high-grade atrioventricular block and hydrops fetalis was established. Due to the high degree of atrioventricular block and the resulting ventricular bradycardia, we had hoped to control the rhythm with

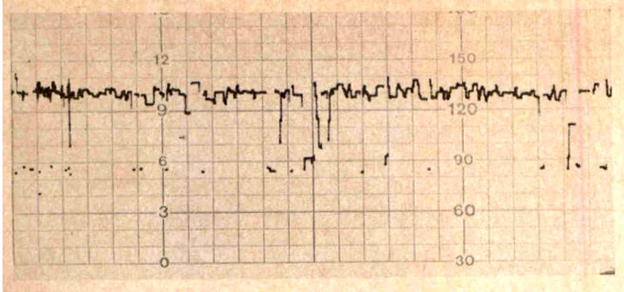

**FIGURE 7.** External fetal heart rate monitor recording from an hydropic fetus at 35 weeks' gestation. A regular rate of 125 beats/min was suggested.

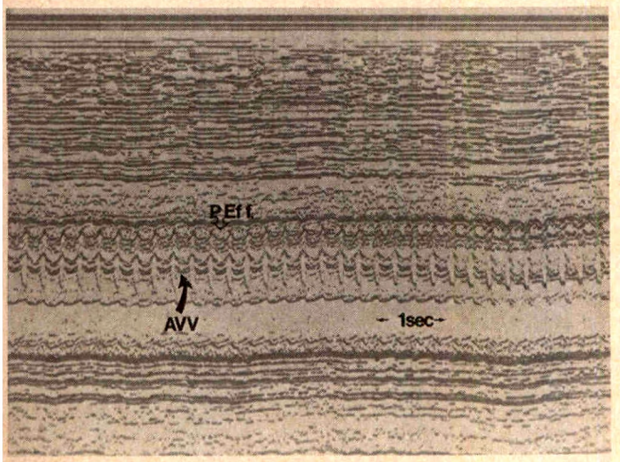

**FIGURE 8.** M-mode echocardiogram at the mid-ventricular level in the same fetus as in Figure 7. The cardiac rhythm is actually supraventricular tachycardia at 250 beats/min. P.Eff = pericardial effusion.

pacemaker therapy, electrical cardioversion, or both. The latter was successful in treating Patient 2, who, while also hydropic, had only 2 to 1 atrioventricular block (Fig. 5).

Patient 3 was initially evaluated due to auscultation of an irregular fetal cardiac rhythm. At the first examination, we noted frequent supraventricular ectopic beats with a protracted episode of bigeminy and several short (3 to 4 beat) runs of tachycardia (Fig. 6). Ten days later, a protracted episode of tachycardia was noted with evidence of early congestive heart failure (pericardial effusion).[22] Due to the extreme degree of prematurity, we elected to treat the arrhythmia through the administration of digoxin to the mother.[23–26] Within 48 hours, the paroxysmal tachycardia and associated effusion had resolved, although atrial ectopic beats did persist. Within 1 week, however, the rhythm was completely normal and remained so until 39 weeks' gestation when, against medical advice, the mother discontinued digoxin. The neonate had frequent atrial ectopic beats at birth and had multiple episodes of supraventricular tachycardia that were eventually controlled with digoxin and propranolol.

**TABLE II Clinical Profiles of Fetuses with Sustained Fetal Arrhythmias**

| Patient | Gestational Age (mo) | Arrhythmia | Clinical Data | Outcome |
|---|---|---|---|---|
| 1 | 34 | Atrial flutter with 5:1 and 6:1 AV block | Polyhydramnios; hydrops fetalis | Stillbirth |
| 2 | 38 | Atrial flutter with 2:1 AV block | Auscultated tachycardia; polyhydramnios; hydrops fetalis | Cesarean section; successful DC cardioversion; alive & well |
| 3 | 27 | Atrial ectopy, bigeminy, & sustained ST | Auscultated arrhythmia; fetal pericardial effusion (early CHF) on ultrasound | Successful transplacental digoxin therapy until 39th week; alive & well |
| 4 | 35 | ST | Fetal tachycardia auscultated | Successful transplacental digoxin therapy; alive & well |
| 5 | 35 | ST | Fetal tachycardia auscultated; polyhydramnios; hydrops fetalis | No reponse to transplacental digoxin & propranolol; cesarean delivery with DC cardioversion and drug therapy; alive and well |
| 6 | 28 | Complex arrhythmia | Polyhydramnios; hydrops fetalis; fetal echo: tetralogy of Fallot | Cesarean delivery 31 weeks, tetralogy of Fallot (cath); ventricular arrhythmias; death at 5 days |
| 7 | 28 | Complete heart block | Fetal bradycardia auscultated; structurally normal heart | Term birth; alive & well |
| 8 | 28 | Complete heart block | Polyhydramnios; hydrops fetalis; isolated levocardia; AV canal defect | Premature (34 weeks) birth; polysplenia syndrome; death at 10 min |
| 9 | 34 | Supraventricular ectopic beats | Arrhythmia auscultated | Term birth; atrial ectopic beats persist; alive & well |
| 10 | 32 | Supraventricular ectopic beats | Arrhythmia auscultated | Term birth; atrial ectopic beats persist; alive & well |
| 11 | 33 | Sinus bradycardia | Polyhydramnios; hydrops fetalis; dilated left atrium and ventricle | Premature delivery; death at 30 min; coronary artery embolus with myocardial infarction |

AV = atrioventricular; cath = cardiac catheterization; CHF = congestive heart failure; DC = direct current; echo = echocardiography; ST = supraventricular tachycardia.

Transplacental therapy with digoxin and propranolol failed to control the supraventricular tachycardia in Patient 5. This patient was delivered at 35 weeks' gestation due to increasing hydrops fetalis. The child had sinus rhythm with frequent atrial ectopic beats at birth

but soon developed reentrant supraventricular tachycardia at 250 to 260 beats/min. This was controlled, with difficulty, with direct-current countershock, digoxin, and verapamil. Over the first 24 hours of life, the arrhythmia was controlled and the child underwent vigorous diuresis. This child has recovered uneventfully and is receiving digoxin and propranolol maintenance therapy. The fetal cardiac rhythm was best demonstrated by M-mode echocardiography. Fetal heart tones in this polyhydramniotic woman were difficult to discern, and the external fetal heart rate monitor suggested that the fetal heart rate was a regular 125 beats/min (Fig. 7), while the echocardiogram correctly demonstrated the rate to be twice that (Fig. 8).

Fetal electrocardiography provided information regarding ventricular depolarization in 2 cases; however, atrial depolarization could not be detected against the background "noise" and the maternal electrocardiogram.[18,27–39]

## Discussion

Fetal cardiac rhythm disturbances are usually first suspected on the basis of auscultatory findings. Due to the inability of transabdominal fetal electrocardiograms to demonstrate atrial depolarization, this technique is unfortunately of limited value in the analysis of cardiac rhythm disturbances. The external fetal heart rate monitor, while accurate for regular rhythms in the "normal" range, may be inaccurate in the presence of fetal tachyarrhythmias (Patient 5).

The echocardiographic studies just described provide a noninvasive means of diagnosing rhythm disturbances and also provide a method of monitoring the response of the fetal rhythm to in utero therapy.[2] The use of 2-dimensional echocardiography in tandem with M-mode echocardiography allows analysis of associated structural cardiac abnormalities, may locate the appropriate planes for M-mode study,[40] and may be used for the detection of associated fetal congestive heart failure.[2]

Our initial studies are consistent with those of previous workers who have suggested that isolated ectopy in the fetus is almost always self-limited and carries a favorable prognosis.[15,16,28,41] Further study through pregnancy is warranted, however, due to the possibility that an isolated ectopic beat could trigger a reentrant tachyarrhythmia.[15,42] Sustained arrhythmias carry a more ominous prognosis, particularly if associated with structural heart disease or in utero congestive heart failure (hydrops fetalis), or both.

Supraventricular tachyarrhythmias associated with congestive heart failure,[24,42–51] when encountered early in gestation with evidence of pulmonary immaturity,[52] can and should be controlled with transplacental digoxin therapy.[15,23–26] Propranolol may be reserved for rhythm control if digoxin therapy alone is unsuccessful.[53,54] The direct administration of antiarrhythmic agents that do not readily cross the placenta (such as verapamil) may also be considered early in gestation. Later in gestation, with evidence of pulmonary maturity or, alternately, in the presence of increasingly severe congestive heart failure, bradyrhythmias, or high-grade atrioventricular block, premature delivery and electrical cardioversion or pacemaker therapy may be preferable.

The fetal echocardiogram, by providing information on heart rate as well as atrioventricular conduction and cardiac structure, may provide diagnostically and therapeutically useful information. The use of this tool for serial noninvasive monitoring of cardiac rhythm may increase the efficacy and safety of in utero therapy with antiarrhythmic agents.

# Assessment of Ventricular Size and Function in Congenitally Corrected Transposition of the Great Arteries

THOMAS P. GRAHAM, Jr., MD, MARK D. PARRISH, MD, ROBERT J. BOUCEK, Jr., MD, ROBERT C. BOERTH, MD, JAMES A. BREITWESER, MD, SANDRA THOMPSON, RN, ROSE M. ROBERTSON, MD, JOHN R. MORGAN, MD, and GOTTLIEB C. FRIESINGER, MD

**Twenty-four quantitative cineangiographic studies were performed in 19 patients with congenitally corrected transposition of the great arteries to assess right and left ventricular size and function. Ages ranged from 7 days to 44 years and associated lesions included ventricular septal defect (13 of 19), pulmonary stenosis (9 of 19), and systemic (tricuspid) valvular insufficiency (7 of 19). Systemic (anatomically right) ventricular end-diastolic volume was within normal limits in most patients and averaged 119% of predicted normal. Pulmonary (anatomically left) ventricular end-diastolic volume also was normal in most patients, averaged 112% of predicted, and was not different from systemic (right) ventricular end-diastolic volume. Systemic ventricular ejection fraction (RVEF) averaged 0.61 ± 0.02 and was not different from pulmonary ventricular ejection fraction (LVEF) (0.65 ± 0.02), but important differences were apparent when age was considered. With exclusion of 2 patients with hypoplastic systemic ventricles and 2 studies performed <6 months after open heart surgery, all 12 patients aged <10 years had a normal RVEF, whereas 2 of 5 patients aged >17 years had a definitely low RVEF and 1 of 5 had a value at the lower limit of normal. In children, systemic and pulmonary ventricular pump function is usually normal in congenitally corrected transposition of the great arteries and any deviation from normal should suggest ventricular hypoplasia or an increase in afterload. After childhood, systemic ventricular dysfunction is more common and may reflect the inability of the anatomic right ventricle to function as the systemic pumping chamber over a normal lifetime in most patients with congenitally corrected transposition of the great arteries.**

Although quantification of ventricular size and function in congenitally corrected transposition of the great arteries can be useful in assessing clinical status both before and after operation, angiocardiographic determination of ventricular volumes and ejection fractions in this condition has been reported previously in only 3 patients.[1] In congenitally corrected transposition of the great arteries there is discordance between the atrial and ventricular connections and between the ventricular and great arterial connections. Thus, the right atrium is connected through a mitral valve to the pulmonary (anatomic left) ventricle which is situated on the patient's right side (assuming normal atrial situs and levocardia). The left atrium receives the pulmonary venous return and is connected to the systemic (anatomic right) ventricle through a tricuspid valve. The systemic ventricle is located on the patient's left and is connected to the aorta, and the anatomic left ventricle is connected to the pulmonary artery. Thus, the anatomic right ventricle functions as the systemic pumping chamber. Frequently, there are associated defects, including ventricular septal defect, pulmonary stenosis, and tricuspid regurgitation as well as partial or complete heart block.

Clinically evident systemic ventricular dysfunction in congenitally corrected transposition of the great arteries is rare until adulthood[2,3] when congestive heart failure frequently associated with tricuspid regurgitation or complete heart block, or both, is a common presentation. Assessment of ventricular size and function not only is desirable for characterization of cardiac

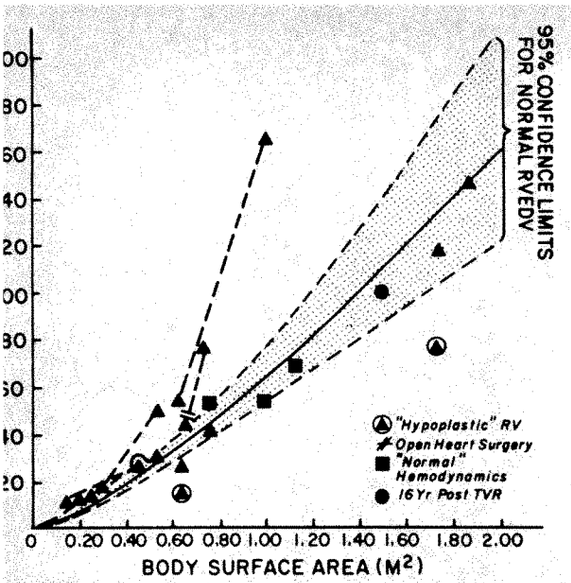
performance in congenitally corrected transposition of the great arteries but also could be useful for comparison with the large number of patients with complete transposition of the great arteries who have undergone intraatrial repair.

In these patients the right ventricle also functions as the systemic pumping chamber, and right ventricular dysfunction has been reported in such patients.[4–6]

The purpose of this investigation was to determine systemic and pulmonary ventricular volumes and ejection fractions during diagnostic cardiac catheterization in patients with congenitally corrected transposition of the great arteries using quantitative cineangiocardiographic techniques and to attempt to relate these variables to other hemodynamic abnormalities.



## Methods

All patients studied at Vanderbilt Hospital from 1971 through 1981 were included in the study. Data were obtained at diagnostic catheterization. Nineteen patients were studied, with 5 patients studied on 2 occasions for a total of 24 studies (Table I). Ages ranged from 7 days to 44 years. Pressures were obtained with fluid-filled catheters with zero referenced to mid-chest. Oxygen saturation was measured by reflectance oximetry and Qp/Qs ratio calculated in patients in whom the pulmonary artery could be entered.

Patient data and hemodynamics are shown in Table I. Thirteen (68%) had ventricular septal defects, 9 (41%) had pulmonary stenosis, and 1 had pulmonary atresia at a preoperative study and a left ventricular to pulmonary artery conduit at the second study with a conduit gradient of 38 mm Hg. One patient had second degree block and 1 had complete heart block at the initial study with a ventricular pacemaker at the second study. The remaining patients were in sinus rhythm with either a normal or a prolonged P-R interval. Tricuspid insufficiency was present in 7 patients (37%) and was graded by the following angiographic criteria. Mild tricuspid insufficiency was defined as minimal atrial opacification during systemic ventricular angiocardiography with filling of only part of the atrium and clearing of contrast within 2 to 3 beats. Moderate tricuspid insufficiency was defined as filling the entire left atrium with clearing of contrast within 3 to 5 beats. Severe tricuspid insufficiency was defined as dense opacification of the left atrium and pulmonary veins which did not clear completely during 5 beats. With these criteria, 1 patient had severe tricuspid insufficiency, 4 had moderate tricuspid insufficiency, and 2 had mild tricuspid insufficiency (Table I). In addition, 1 patient (Patient 18) had tricuspid valve replacement 16 years before the present study, and 1 patient (Patient 16) had significant aortic insufficiency both before and after tricuspid valve replacement. Clinical cyanosis was present in 4 patients with mild desaturation in 2 additional patients.

In this report left ventricle refers to the anatomic left (pulmonary) ventricle and right ventricle refers to the anatomic right (systemic) ventricle. Left ventricular peak systolic pressure was elevated when compared with normal right (pulmonary) ventricular pressure in all but 5 patients. These 5 patients had pressure near the upper limit of normal (32 to 40 mm Hg). End-diastolic pressure in the pulmonary ventricle was ≥12 mm Hg in 5 patients, and end-diastolic pressure in the right (systemic) ventricle was ≥12 mm Hg in 11 patients.

Right and left ventricular volume determinations were performed using angiocardiographic techniques described previously.[7,8] Sixteen patients had levocardia and 3 had dextrocardia. Anteroposterior and lateral views were used in all patients. The area-length method was used for the pul-

ary ventricle[7] and Simpson's rule method for the systemic icle.[8] All data were calculated during sinus rhythm, and ic or immediate postectopic beats were not used. In 20 e 24 studies, angiograms were suitable for analysis of both icles. In 4 studies, only right ventricular angiograms were n and in 3 of these studies a magnification grid was not so that only ejection fraction data were available. Two nts with hypoplastic right ventricles[1] are included in the hic analyses and in the tables but were excluded from the stical analyses as indicated in the results.

mparison of right and left ventricular data from patients nom both were available was performed by paired $t$ test $p < 0.05$ considered the lower level of significance. Linear ession analysis was performed to determine correlates of diastolic volume and ejection fraction in terms of age, ee of shunt, and degree of cyanosis.

## Results

gure 1 shows systemic ventricular end-diastolic me as a function of body surface area, with normal es from previous data[8] shown for comparison. teen of 21 studies (62%) are within the 95% confie limits of normal. Three patients have values w normal; all have ventricular septal defect plus re pulmonary stenosis and 2 (indicated by circled ngles) have been reported on previously as examples ypoplastic systemic ventricles.[1] Five values are inased, and all of these patients had ventricular septal ct with large systemic to pulmonary shunts or lerate to severe tricuspid insufficiency.

Figure 2, systemic ventricular end-diastolic volume own as a percentage of predicted normal[8] with pats grouped by the major hemodynamic lesion or ns at the time of study. Four patients had insigant hemodynamic defects. Two had trivial pulary stenosis (left ventricle-pulmonary artery gradient 17 to 22 mm Hg), 1 had mild tricuspid insufficiency, and a 23 year old girl had had tricuspid valve replacement 16 years previously. At the time of this study, she had no tricuspid insufficiency and no significant wedge to right ventricular end-diastolic pressure gradient. These patients had normal volumes.

The second group shown in Figure 2 had ventricular septal defects with large left to right shunts, and 4 of 5 patients had a large systemic ventricle.

The third group of patients had ventricular septal defect plus pulmonary stenosis with a balanced shunt resulting in no significant cyanosis, defined here as a systemic oxygen saturation ≥85% (range 85 to 100%, mean 93%). Three of 4 patients have normal-sized right ventricles and 1 patient has a small chamber, 63% of the predicted normal size. The fourth group in Figure 2 consists of patients with ventricular septal defect plus severe pulmonary stenosis resulting in clinical cyanosis and a systemic oxygen saturation ≤82% (range 71 to 82%, mean 76%). These patients have normal or small

**TABLE II Comparison of Pulmonary and Systemic Volume Variables in Patients for Whom Both Variables Were Calculated (17 Studies in 14 Patients)***

| | LV | RV | |
|---|---|---|---|
| End-diastolic volume (% of normal) | 112 ± 7 | 119 ± 11 | NS |
| Ejection fraction | 0.65 ± 0.02 | 0.61 ± 0.02 | NS |

* Excluded from comparison were 2 patients with a hypoplastic right ventricle, 2 studies performed within 6 months after open heart surgery, and 4 studies in 3 patients with no left ventricular angiograms.

Values are mean ± standard error of the mean. LV = left (pulmonary) ventricle; NS = not significant ($p > 0.05$); RV = right (systemic) ventricle.

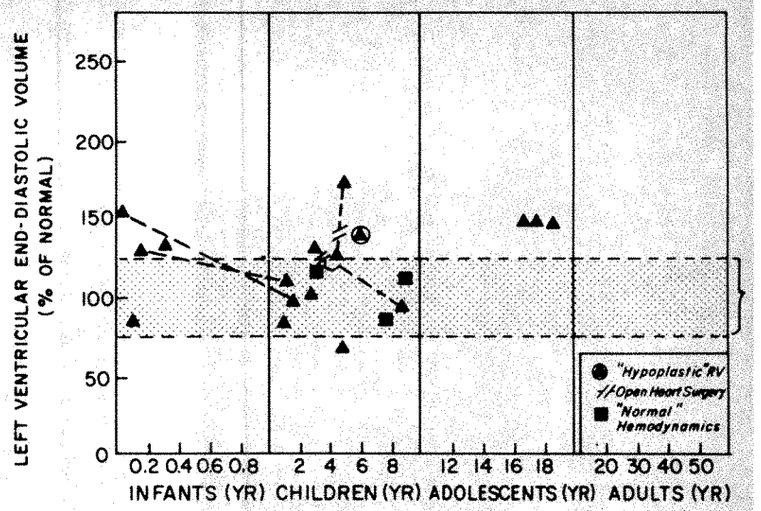

**FIGURE 3.** Left (pulmonary) ventricular end-diastolic volume as a function of percentage of predicted normal. The normal range indicates the values for patients with normal left ventricles. RV = right ventricle.

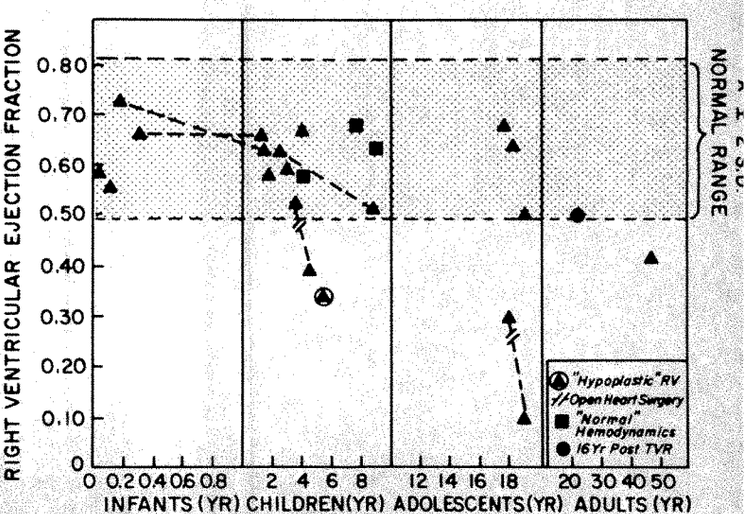
ventricles, with the 2 patients with hypoplastic right ventricles previously reported[1] shown here. The fifth group consists of 2 patients with significant tricuspid insufficiency. These patients have markedly enlarged ventricles, as would be predicted.

Figure 3 shows pulmonary (anatomic left) ventricular end-diastolic volume plotted as a percentage of predicted normal values. Nine patients who ranged in age from infancy to adolescence had definite enlargement of the left ventricle. Enlargement appeared to be related to systemic to pulmonary shunting at the ventricular level in 6 patients with Qp/Qs $\geq$1.7 in 5 of 6 in whom oximetry data were available and with all patients showing clinical evidence of increased Qp. The 2 patients with hypoplastic right ventricles also had enlarged left ventricles. One of these patients (aged 5) had a tight pulmonary artery band and 1 patient (aged 19) had severe pulmonary stenosis with systemic hypertension and left and right ventricular peak systolic pressure of 165 mm Hg. Enlargement of the left ventricle in these patients was undoubtedly related to the small systemic ventricle and to the pulmonary to sys temic shunting, with the left ventricle supplying par of the systemic output. In addition, these patients ha chronic, severe pressure overload which also possibl contributed to the left ventricular enlargement.

Table II shows a comparison of left and right end diastolic volumes in 17 studies in 14 patients in whor both variables could be calculated. The 2 patients wit hypoplastic systemic ventricles as well as 1 patien studied 4 months after open heart surgery were ex cluded from this analysis. Mean values for both pul monary (left) and systemic (right) ventricular volume were slightly increased above normal, but compariso of the 2 ventricles showed no significant difference i size.

Systemic ventricular ejection fraction in all 24 studie is shown in Figure 4. The ejection fraction was withi normal limits in 19 of the 24 studies. Only 2 patient aged <10 years had an ejection fraction less than nor mal. One child was studied for pulmonary atresia an ventricular septal defect <6 months after open hear



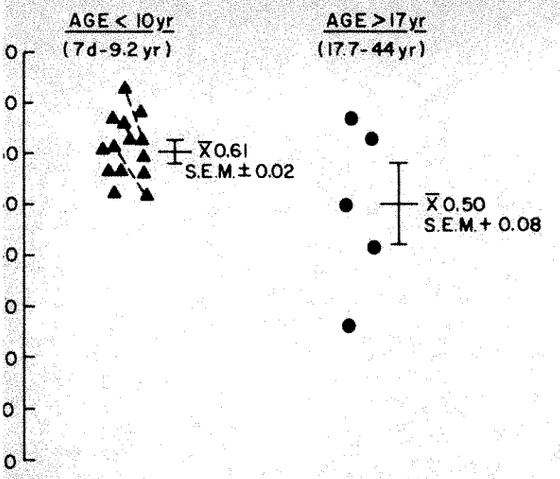


**FIGURE 4.** Right (systemic) ventricular ejection fraction shown for 4 age groups. Normal range is for patients with a normal right ventricle functioning as the pulmonary ventricle. Abbreviations as in preceding figures.

**5.** Right (systemic) ventricular ejection fraction in congenitally d transposition shown for patients aged <10 years versus those 17 years. Patients excluded from this figure include those with lastic right ventricle and those with recent open heart surgery. iations as in preceding figures.

y. This child had an open ventricular septal defect ıoderate tricuspid insufficiency at the time of The recent open heart surgery may have con- ed to the low ejection fraction. The only other ıt with a low ejection fraction in the young age was the patient with severe hypoplasia of the right cle.[1]

ong adolescents and adults, 3 studies in 2 patients d a low ejection fraction, and 2 additional patients n ejection fraction at the lower limit of normal. patient with a markedly low ejection fraction was ·d originally at another hospital at 6 years of age ›und to have no hemodynamic abnormalities. lmonary (left) ventricular ejection fraction (Fig. s normal in 14 of 20 studies. Low left ventricular on fractions were present before and after at- ·ed repair in the 3 year old with pulmonary atresia ı the 19 year old with a small right ventricle and ·e left ventricular pressure overload. This variable was greater than normal in 4 studies in 3 children aged 3.5 to 8.5 years.

Left and right ventricular ejection fractions (Table II) in the 17 studies in 14 patients in whom both variables could be calculated were not significantly different. Right ventricular ejection fraction calculated in 20 patients, including 3 in whom left ventricular studies were unavailable, was 0.58 ± 0.02 (mean ± standard error of the mean). The latter data again exclude patients with hypoplastic right ventricles as well as patients with open heart surgery performed in the 6 months before study.

Attempts to determine possible correlations of the volume determinations and ejection fraction data with other variables also were made. No significant linear relation was found between right ventricular end-diastolic volume and oxygen saturation or age. There was a significant correlation between right ventricular end-diastolic volume and Qp/Qs ratio in patients with no significant tricuspid insufficiency. The r value for this relation was 0.645. In addition, the right ventricular stroke index/left ventricular stroke index calculated from the angiographic studies also was compared with the Qp/Qs ratio. Again in the same group of patients, the correlation was significant: r = 0.648. These data indicate that right ventricular size and right ventricular/left ventricular output ratios do show a significant correlation with pulmonary blood flow when patients with severe tricuspid insufficiency are excluded from analysis. An attempt also was made to determine if there were significant correlations of right ventricular ejection fraction with age, right ventricular end-diastolic volume, or systemic oxygen saturation. No significant correlations were found using regression analysis techniques.

## Discussion

Our data demonstrate that the majority of patients up to their young adult years with congenitally corrected transposition of the great arteries have systemic ventricles that are normal or near normal in size. In addition, 4 patients with relatively normal hemodynamics showed values that were well within the normal range.

Patients who did have abnormalities of volume fell into 2 categories. Patients with ventricular septal defects and large systemic to pulmonary shunts as well as patients with moderate to severe tricuspid (systemic) atrioventricular valvular insufficiency had large systemic ventricles. Patients with congenitally corrected transposition of the great arteries plus ventricular septal defect and large left to right shunts have analogous hemodynamic loads on the systemic ventricles as do patients with normally related great arteries and ventricular septal defects who demonstrate left ventricular enlargement which correlates well with the degree of left to right shunt.[9,10] In addition, patients with congenitally corrected transposition of the great arteries plus tricuspid insufficiency have systemic ventricular hemodynamic loads that are analogous to those of patients without congenitally corrected transposition of the great

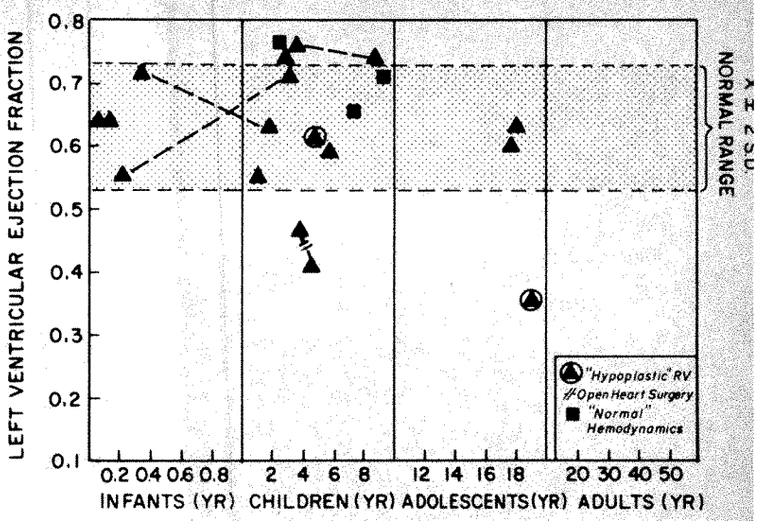

**FIGURE 6.** Left (pulmonary) ventricular ejection fraction in patients with congenitally corrected transposition of the great arteries. Normal ranges for patients with a normal left ventricle. RV = right ventricle; S.D. = standard deviation.

arteries who have mitral insufficiency and left ventricular enlargement.

Patients with congenitally corrected transposition of the great arteries and ventricular septal defect plus pulmonary stenosis had normal or decreased systemic ventricular volume. These patients have analogous hemodynamics to patients without congenitally corrected transposition of the great arteries who have tetralogy of Fallot and who have normal or mildly decreased left ventricular volumes with left ventricular size showing a direct correlation with pulmonary blood flow.[11,12] Finally, 2 of 19 patients (10.5%) showed definitely small or hypoplastic right ventricles. Both of these patients have been reported on previously[1] and had decreased pulmonary flow due to pulmonary stenosis or pulmonary artery banding. A similar degree of left ventricular hypoplasia has been reported in tetralogy of Fallot.[13]

The anatomic left or pulmonary ventricle of patients with congenitally corrected transposition was also normal or near normal in size in the majority of patients studied. Most of these pulmonary ventricles were under high pressure (Table I). In our laboratory, values for normal left or normal right ventricular end-diastolic volume are not significantly different. In addition, the right ventricle in children with high pressure secondary to pulmonary stenosis is not enlarged.[8] Therefore, the mean values for systemic and pulmonary ventricular volume in patients with congenitally corrected transposition will be normal or near normal whichever ventricle is chosen for comparison. In this study, only patients with large ventricular systemic to pulmonary shunts or hypoplastic systemic ventricles had enlarged pulmonary ventricles.

The ejection fraction for left (pulmonary) ventricles in patients with corrected transposition was within normal limits with 2 exceptions. This value was decreased preoperatively in a patient with pulmonary atresia and continued to be decreased postoperatively. In addition, 1 other patient with severe pulmonary stenosis had a low left ventricular ejection fraction. Thus, in the majority of patients with congenitally corrected transposition without ventriculotomy or a severely increased afterload, the ejection fraction of the pulmonary ventricle was normal.

Although the systemic or right ventricular ejection fraction was normal in most patients, it was abnormal only in 2 of 13 patients (15%) who were <10 years of age but was abnormal in 2 of 6 patients (33%) >17 years of age and at the lower limit of normal in 2 additional older patients. Moreover, the 2 children with a low ejection fraction had a hypoplastic right ventricle and recent open heart surgery, conditions that could explain the decreased ejection fraction. These data suggest that an increasing incidence of systemic ventricular dysfunction may be present in older patients with congenitally corrected transposition.

A number of reports have documented adults usually aged 20 to 40 years with congenitally corrected transposition of the great arteries who present with congestive heart failure frequently associated with tricuspid (systemic atrioventricular valvular) insufficiency, complete heart block, or atrial arrhythmias, or a combination of these.[2,3,14–22] Most of these patients were asymptomatic earlier in life. Our data suggest that such patients probably have a normal ejection fraction in childhood which gradually worsens with progressive deterioration of the systemic ventricle in adult life.

The contribution of progressive tricuspid insufficiency to systemic ventricular dysfunction in congenitally corrected transposition of the great arteries is unclear. The structure and muscular configuration of the systemic ventricle may predispose to tricuspid insufficiency when it is forced to function in the systemic circuit. Most patients who have isolated mitral insufficiency and do not have corrected transposition can tolerate moderate to severe mitral insufficiency for extended periods before ventricular dysfunction occurs. The patient in our study who had a normal cardiac catheterization at 6 years and presented with severe

ongestive heart failure at 18 years had the development of both ventricular dysfunction as well as tricuspid insufficiency between the 2 studies.

These data are of considerable interest in terms of follow-up study of patients who have had intraatrial repair of complete transposition and who also have the anatomic right ventricle function as the systemic ventricle after operation. Many of these children have systemic ventricular dysfunction on angiographic measurements, and the overall mean value for right ventricular ejection fraction in patients with no significant hemodynamic abnormalities after surgery is approximately 45%[4–6,23] as compared with the 61% ejection fraction found in this study in patients with congenitally corrected transposition. Thus, the 45% right ventricular ejection fraction in children with complete transposition is clearly abnormal when compared with "nature's model" for a right ventricle functioning as the systemic pumping chamber. These patients with postoperative transposition deserve careful follow-up study to determine the incidence of clinically significant systemic ventricular dysfunction in adolescence and early adulthood and the correlates of such dysfunction.

Several potential methodologic problems arise with the studies presented. The ventricular volume data were obtained using angiographic methods that have been validated for normal left and right ventricles. Postmortem ventricular casts from patients with congenitally corrected transposition were unavailable for in vitro volume determinations. However, the shape of the pulmonary ventricle in congenitally corrected transposition of the great arteries is similar to that of the normal left ventricle, suggesting that the area-length method is applicable.

Right ventricular volume studies have been applied in patients with various congenital abnormalities including complete transposition before and after repair.[4–6,23] Comparison of cineangiographic right and left ventricular outputs with indicator dilution output in such patients shows an excellent correlation, and thus an in vivo validation of volume-derived output has been performed.[5] In addition, we compared angiographic right ventricular ejection fractions with radionuclide data in postoperative transposition as well as in congenitally corrected transposition and found an excellent correlation ($r = 0.98$, standard error of the estimate $\pm 0.03$) with no significant difference between the values obtained by the 2 methods.[24]

A second potential problem is the use of the ejection fraction as a measurement of ventricular performance. The ejection fraction is determined not only by contractile state but also by preload and afterload. In the 3 patients with small ventricles in this study, a depressed ejection fraction could be due to the small volumes and would not necessarily indicate ventricular muscle dysfunction. In the remaining patients with normal or increased volume, afterload must be considered. Systemic vascular resistance could be calculated in 21 of the 24 studies reported. This variable was greater than the upper limit of normal in our laboratory (>30 units/m$^2$) in only 3 of the 21 studies. One abnormal value for systemic vascular resistance (32 units/m$^2$) was in the 23 year old woman who had had tricuspid valve replacement 13 years previously. Her ejection fraction was slightly above normal. The other 2 values for elevated systemic vascular resistance were in the 18 year old man with a severely decreased ejection fraction (0.26 and 0.07) in 2 studies. The systemic vascular resistance at the first study was 37 and at the second study, 62. Because of the patient's low cardiac indexes (2.0 and 1.0) calculated at both studies, these values for systemic vascular resistance may be falsely high. At such low cardiac indexes, the error in calculation can be considerable. Nevertheless, this patient's low systemic ventricular ejection fractions may have been related in some measure to the elevated systemic vascular resistance. In addition, the decrease in ejection fraction from 0.26 and 0.07 after tricuspid valve replacement may have been largely due to the elimination of a low resistance pathway for systemic ventricular ejection into the left atrium.

In contrast, only 1 patient had a systemic resistance that was less than our lower limit of normal (<15 units/m$^2$). That patient was a 9 year old girl with severe tricuspid insufficiency and marked ventricular dilation whose ejection fraction was within normal limits. Thus, neither an abnormally low nor an abnormally high systemic vascular resistance appears to have been related to the overall results in terms of systemic ventricular ejection fraction.

**Conclusions:** (1) Systemic (right) ventricular size and ejection fraction are with normal limits in most infants and children with congenitally corrected transposition. Patients in this age group who have an increase in systemic ventricular size usually have significant systemic to pulmonary shunting or tricuspid insufficiency. (2) Evidence suggests that systemic ventricular ejection fraction may decrease with age. Further longitudinal data are needed in this regard. (3) The systemic ventricular ejection fraction is considerably higher in young patients with congenitally corrected transposition than in children studied after intraatrial repair of complete transposition of the great arteries. This difference implies that other factors such as preoperative myocardial hypoxia or intraoperative myocardial ischemia may contribute to the abnormal systemic ventricular function in patients with complete transposition. (4) Left (pulmonary) ventricular size and ejection fraction are normal in the majority of infants and children. Increases in left ventricular size usually are associated with ventricular septal defect, hypoplastic right ventricle, or a marked increase in ventricular afterload.

# ediatric Population: Evaluation by Radionuclide ngiocardiography

)GER A. HURWITZ, MD, SALVADOR TREVES, MD, MICHAEL FREED, MD,
)NALD A. GIROD, MD, and RANDALL L. CALDWELL, MD

**e ability to quantitate aortic (AR) or mitral gurgitation (MR), or both, by radionuclide angio- rdiography was evaluated in children and young lults at rest and during isometric exercise. gurgitation was estimated by determining the tio of left ventricular stroke volume to right ven- cular stroke volume obtained during equilibrium ntriculography. The radionuclide measurement as compared with results of cineangiography, with od correlation between both studies in 47 of 48 tients. Radionuclide stroke volume ratio was used classify severity: the group with equivocal gurgitation differed from the group with mild gurgitation ($p < 0.02$); patients with mild regurgi- tion differed from those with moderate regurgita- n ($p < 0.001$); and those with moderate regurgitation differed from those with severe regurgitation ($p < 0.01$). The stroke volume ratio was responsive to isometric exercise, remaining constant or increasing in 16 of 18 patients. After surgery to correct regurgitation, the stroke volume ratio significantly decreased from preoperative measurements in all 7 patients evaluated. Results from the present study demonstrate that a stroke volume ratio >2.0 is compatible with moderately severe regurgitation and that a ratio >3.0 suggests the presence of severe regurgitation. Thus, radionuclide angiocardiography should be useful for noninvasive quantitation of AR or MR, or both, helping define the course of young patients with left-side valvular regurgitation.**

rdiac catheterization is frequently necessary to aluate the degree of MR or AR in children, because ese lesions are difficult to quantitate by noninvasive ethods. Furthermore, it may be helpful to evaluate ch patients during drug intervention, during exercise, by serial investigations, thus increasing the desirility for a noninvasive technique. Such evaluation is ost important when managing younger patients, in om surgical treatment should be considered at a time en preservation of long-term myocardial function can accomplished. However, early surgical intervention these lesions is seldom recommended because valve placement is often required to significantly reduce gurgitation.

Noninvasive laboratory evaluation of adults with lvular regurgitation has recently been supplemented echocardiography, exercise testing, and radionuclide giocardiography.[1–3] The radionuclide technique has en useful in evaluating systolic pump function, wall otion, and regurgitation fraction.[4–7] The purpose of e present study is to investigate the role of radionude angiocardiography in quantitation of AR or MR in young patients by (1) a comparison of the radionuclide estimate of regurgitation with the estimate by cineangiography; and (2) an evaluation of possible change in regurgitation during isometric exercise and after cardiac surgery to correct regurgitation.

## Methods

**Patient population:** The study group consisted of 48 children and young adults referred to the Division of Nuclear Medicine at Children's Hospital Medical Center (CHMC) and Riley Hospital for Children at Indiana University (IU) for further evaluation of documented aortic or mitral valve abnormalities, or both, including some degree of regurgitation. Patients shown by cardiac catheterization to have intra- or extracardiac shunting, tricuspid regurgitation, or pulmonary regurgitation were excluded. The radionuclide estimate of valvular regurgitation was compared with the cineangiographic estimate; only patients with both studies performed within 4 months were included. The age range of the 19 CHMC patients was 0.5 to 26 years (median 13) and of the 29 IU patients 1 to 16 years (median 7). The valvular abnormality was congenital in 42 patients and rheumatic in 6. At the time of radionuclide study the aortic valve was predominantly involved in 29 patients and the mitral valve in 19. Of the total group, 37 patients had previous cardiac surgery and 26 had defects in addition to the valvular regurgitation (Table I). Seven patients were evaluated by radionuclide angiocardiography before and after operation to relieve regurgitation, but not all 7 had postoperative cineangiography. Eighteen patients underwent radionuclide angiocardiography while performing isometric exercise. Three of these had clinical

diagnosis of AR or MR but no current, confirmatory cardiac catheterization; 15 had resting studies included in the initial comparison between radionuclide and cineangiographic estimate of regurgitation.

**Radionuclide angiocardiography:** All 48 patients had estimation of resting left ventricular ejection fraction by gated equilibrium ventriculography. At CHMC, red blood cells were labeled in vivo using 1 to 2 mg stannous pyrophosphate (Pyrolite, New England Nuclear) followed in 20 minutes by 200 μCi/kg technetium-99m as pertechnetate labeled onto 2 to 3 ml of the patient's own red blood cells.[8] Radionuclide ventriculograms were obtained using an Anger scintillation camera and a high-sensitivity, straight-bore collimator slanted at 30°. Five minutes after injection of the radiopharmaceutical, the camera was positioned in a modified left anterior oblique projection (30° caudal tilt).[9] Ten million counts were acquired in matrix mode, using a matrix size of 64 × 64 elements. Data were acquired on magnetic disk using a standard digital computer and nuclear medicine software (PDP 11/34 and Gamma-11 system, Digital Equipment), with a 15% window centered on the technetium-99m photo-peak. Data acquisition was gated to the patient's electrocardiogram. Initially, left ventricular ejection fraction was calculated. The cardiac cycle was divided into 57 frames, with data acquisition triggered by the patient's R wave.

The end-diastolic left ventricular perimeter was drawn manually, and left ventricular background regions were defined automatically.[10] Briefly, this entails estimation of the left ventricular background per cell as the mean counts per cell in 3 background regions surrounding the left ventricle and calculated on the end-systolic frame. This background value was then subtracted from each cell of the end-diastolic and end-systolic frames. Occasional changes in background regions were necessary to avoid excessive splenic activity, or, in smaller children, to keep the "septal" background region out of the right ventricular cavity by narrowing the region. End-systolic and end-diastolic images were selected from time activity curves; these images were derived by adding frames (usually 2 or 3) to most closely approximate a summed 50 ms interval.

At IU, red blood cells were labeled in vitro; after withdrawal of 2 to 3 ml of the patient's blood, 200 μCi/kg technetium-99m as pertechnetate was labeled onto a small bolus of blood (less than 0.5 ml) and then injected. Imaging was performed in a left anterior oblique projection to obtain best septal delineation. A mild caudal tilt (15 to 20°) was employed. Images were acquired with an Anger camera and a medium-sensitivity, parallel-hole collimator. Data were collected on a magnetic disk and interpolated to 64 × 64 matrix. Acquisition was terminated when 1 of the 28 frames from each cardiac cycle had 250,000 counts. Analysis was performed using commercial software programs (Medical Data Systems).[11] Semiautomatic regions of interest were generated over the left ventricle, and background was automatically generated lateral and inferior to the left ventricle. From these regions of interest, time activity curves were derived.

A stroke volume ratio (left ventricular counts to right ventricular counts) was calculated from activity ejected from each ventricle by a similar technique at both institutions. This ratio was determined from the stroke volume image and was not background-corrected.[4–7] The stroke volume image itself was obtained by subtracting the end-systolic frame (or frames) from the end-diastolic frame (or frames). Separate ventricular regions of interest were then drawn from this image. An attempt was made to include all right ventricular activity, including the outflow area (Fig. 1). Boundaries could be established with reasonable certainty using the paradox image, which provided atrial and great vessel contours by subtracting end-diastolic frames from end-systolic frames. Thus, remaining activity was presumably nonventricular when present at the upper or outer margin of the cardiac area (ventricular aneurysms might also have paradoxic activity).

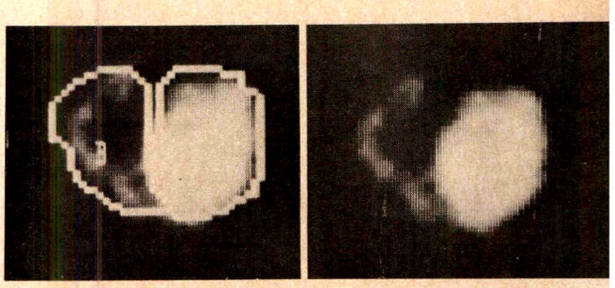
**TABLE I Associated Lesions in All Patients With Radionuclide and Cineangiographic Comparison**

| Lesion | CHMC | IU | Total |
|---|---|---|---|
| AS | 4 | 4 | 8 |
| Co A | 1 | . . . | 1 |
| PO AS | 8 | 9 | 17 |
| PO AVR | 2 | . . . | 2 |
| PO VSD; AR | 2 | 2 | 4 |
| PO MVR | 2 | 3 | 5 |
| PO ECD | . . . | 10 | 10 |
| PO VSD, TGA | . . . | 1 | 1 |
| Total | 19 | 29 | 48 |

AS = aortic stenosis; AVR = aortic valve replacement; Co A = coarctation of the aorta; ECD = endocardial cushion defect; MVR = mitral valve replacement; PO = postoperative; VSD, AR = ventricular septal defect and aortic regurgitation; VSD, TGA = ventricular septal defect and transposition of the great arteries (Rastelli procedure).

The effects of isometric exercise were analyzed in 20 patients. A hand-grip dynamometer was constantly squeezed at 25 to 33% of single maximal effort for a 2-minute warm-up, with the collection of data for 2 to 3 minutes in the same projection as that used for the resting study. Count acquisition was 20 to 25% of that in the resting study, and provided sufficient data to allow stroke volume images to be clearly discernible in 18 of the 20 patients. Pulse, blood pressure, and electrocardiogram were monitored during and after isometric exercise.

**Data analysis:** Stroke volume ratio, defined as counts ejected from the left ventricular region by counts ejected from the right ventricular region, was compared with the cineangiographic degree of regurgitation routinely classified by the staff cardiologist and radiologist as slight, mild, moderate, or severe. This cineangiographic estimate is subjective, being based on a visual interpretation of regurgitation. The interpretation adopted at both CHMC and IU is a modification of the classification proposed by Sellers et al,[12] with present grading as follows: *slight* (or trace) has minimal opacification, with clearing of the proximal chambers in 1 beat, and may be only artifactual; *mild* has opacification not clearing in 1 cycle, is not progressive, but is definitely abnormal; *moderate* has progressive filling of the proximal chamber and is of considerable significance; *severe* occurs when the proximal chamber fills within 1 or 2 cycles, allowing complete visualization with opacity as great as the distal chamber. Individual stroke volume ratios were placed into these angiographic classifications, with compilation of mean and standard deviations for each group. These values were then compared by Student's *t* test



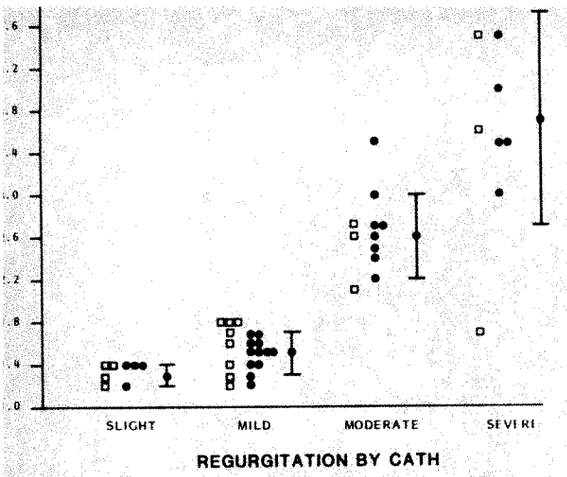


**FIGURE 1.** Stroke volume image with ventricular regions of interest. Note small right ventricular (B) stroke volume activity compared with that of left ventricle (A) in a 10-year-old with moderate to severe AR.

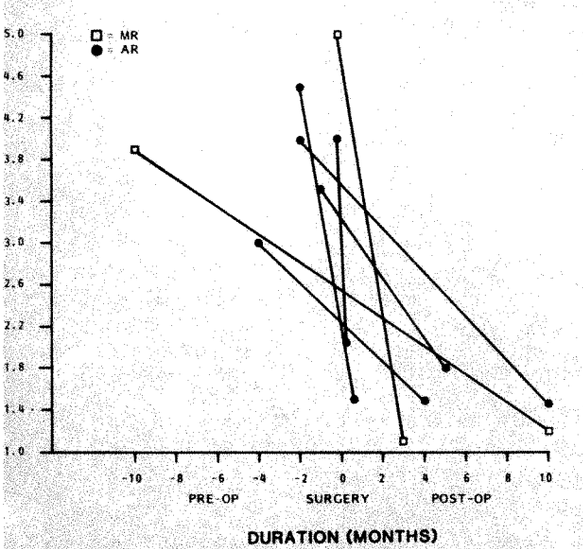

**IE 2.** Stroke volume ratio (SVR) plotted against degree of valvular gitation assessed by angiography performed during cardiac terization (cath). AR and MR = aortic and mitral regurgitation, ctively.

ıpaired data. When isometric exercise was performed, volume ratios at rest and during exercise were com- using Student's *t* test for paired data. Regression sis was used to test a possible relation between stroke ıe ratios and ejection fraction.

## Results

**timate of regurgitation by stroke volume ratio:** /-eight patients had comparison of AR or MR, or estimated by radionuclide techniques and cine- ıgraphy. Previously, the left ventricular to right icular stroke volume ratio in children without ılar regurgitation was calculated up to 1.4 at CHMC g a slant-hole collimator) and up to 1.5 at IUMC g a parallel-hole collimator). When classified ac-

**RE 3.** Stroke volume ratio (SVR) in 7 patients studied by radio- le angiocardiography before (pre-op) and after (post-op) surgery rect valvular regurgitation.

stroke volume ratio of patients with slight (equivocal) regurgitation was 1.3 ± 0.1; with mild regurgitation, 1.5 ± 0.2; with moderate regurgitation, 2.6 ± 0.4; and with severe regurgitation, 3.7 ± 1.0. The group with slight regurgitation was not statistically different from our patients without regurgitation, but was significantly different from those with definite but mild regurgitation ($p < 0.02$). The group with mild regurgitation differed from the group with moderate regurgitation ($p < 0.001$); the moderate group also differed from the group with severe regurgitation ($p < 0.01$). Generally, any patient with a stroke volume ratio >2.0 had at least moderate regurgitation, and if the ratio were >3.0, severe regurgitation was likely (Fig. 2). The radionuclide estimate of regurgitation correlated well with cineangiographic estimate in 47 of 48 patients.

**Isometric exercise:** Isometric exercise resulted in a group heart rate increase of 6.2% (range 3 to 12), systolic blood pressure increase of 14.8% (range 5 to 32), and diastolic blood pressure increase of 5.5% (range 0 to 18). Isometric exercise increased mean stroke volume ratio from 2.5 ± 0.8 to 2.8 ± 1.0 ($p < 0.05$) in the 18 patients. The stroke volume ratio remained constant or increased in 16 of 18 patients during exercise.

**Effect of surgery:** Seven patients (5 with aortic and 2 with mitral valve disease) were studied before and after surgery. One patient had aortoplasty, and the other 6 underwent valve replacement. The stroke volume ratio decreased significantly in each patient (Fig. 3). This change could be seen as early as 2 weeks postoperatively.

## Discussion

Management of asymptomatic patients with AR or MR remains imprecise, because the goal is often preservation of long-term myocardial function. Valve replacement in children is dangerous; during the first 20 years of open-heart surgery, aortic or mitral valve replacement carried a 30% risk in the pediatric population,[13] and current reports cite perioperative mortality of 10%.[14] Also, progressive valvular obstruction may occur with growth, necessitating repeat valve replacement.[15] To lessen the possibility of embolization and the necessity for anticoagulation, homo- and heterograft valves were considered logical prostheses for children. Unfortunately, in a significant number of these valves tissue degeneration or calcification developed, especially in children.[14,16]

Accurate noninvasive quantitation of regurgitation would help determine an optimal management schedule for children with aortic or mitral valvular lesions. Recently, estimation of valvular regurgitation in adults by radionuclide ventriculography showed good correlation when compared with estimation by cardiac catheterization.[4–7] The radionuclide estimate, based on ventricular count output, correlated well with both hemodynamic and angiographic estimate of regurgitation. Therefore, we applied these radionuclide techniques to study children and young adults. Analysis of the radionuclide study was performed without knowledge of the severity of deformity suspected clinically or estimated by cardiac catheterization.

The stroke volume ratio was used to estimate regurgitation. Theoretically, this ratio should be unity. However, complex right ventricular anatomy, magnified in the left anterior oblique projection, makes it difficult to accurately image the entire right ventricle. When totally eliminating the right atrium, a segment of pulmonary outflow may be sacrificed. Also, the extension of right ventricle curving posteriorly around the septum in this projection may be amputated. Normal adults, our normal patients, and those in this study with equivocal valvular regurgitation have a stroke volume ratio of 0.9 to 1.5.[9,10] Thus, a stroke volume ratio >1.4 to 1.5 must be present to diagnose definite regurgitation. There was overlap between estimated stroke volume ratios of normal patients and those with slight regurgitation. However, the radionuclide technique was capable of identifying those with more significant regurgitation and also of providing quantitative classification. Accuracy of quantitation appeared similar for patients with either aortic or mitral valve regurgitation, although the smaller subgroups precluded statistical verification.

Overall, there was excellent correlation between radionuclide and cardiac catheterization estimate of regurgitation in all but 1 patient, who had previous aortic valvotomy. He also had a bizarre left ventricle, long segment subaortic stenosis, and intermittent atrial fibrillation and was considered clinically to have congestive heart failure despite a high left ventricular ejection fraction determined by both cardiac catheterization and radionuclide angiocardiography. The inconsistency in the estimation of regurgitation was not totally unexpected, because previous work has shown that when discrepancy between catheterization and radionuclide quantitation occurs, it is usually in those patients with arrhythmia or severe congestive heart failure.[6]

Stroke volume ratio was also responsive to apparent surgical intervention. Radionuclide evaluation of 7 postoperative patients demonstrated significantly less regurgitation and correlated with cineangiographic results in the 4 patients studied postoperatively by cardiac catheterization. A decrease in stroke volume ratio was documented in 1 patient at the first radionuclide test 2 weeks after surgery. Stroke volume ratio often changed before any measurable increase in left ventricular ejection fraction. This alteration in regurgitation before improvement in myocardial function is common after valve replacement in adults.[17]

The role of isometric exercise as an adjunct in the evaluation of patients with AR or MR was investigated. Generally, the stroke volume ratio was sensitive to the increased afterload imposed by isometric exercise. After stress, the left ventricular ejection fraction significantly decreased in 2 patients with normal resting values. However, the total group of patients showed no statistical relation between resting or stress stroke volume ratio and ejection fraction. This negative relation could be expected because resting myocardial function is usually preserved in patients with left-sided valvular regurgitation until late in the disease.[18] Despite large ventricular dimensions, a large stroke volume may result in a normal cardiac output and ejection fraction. When an abnormal ejection fraction is found, function is usually severely impaired. Thus, candidates for surgery might be those whose ventricular function or degree of regurgitation shows a significant change during serial studies or in response to exercise, because abnormal response to stress has been demonstrated in adults requiring valve replacement.[19] Furthermore, there are data suggesting that even mild congestive heart failure significantly alters the surgical prognosis.[20]

The present study demonstrates that radionuclide angiocardiography is safe and effective in quantitating regurgitation during evaluation of ventricular ejection fraction in children with AR or MR. Serial resting studies using this technique, coupled with evaluation during stress, may help define the course of such patients, providing objective data in a relatively noninvasive manner.

# ıupravalvular Aortic Stenosis

## . 20-Year Clinical Perspective and Experience With Patch Aortoplasty

REG FLAKER, MD, DOUGLAS TESKE, MD, JAMES KILMAN, MD, DON HOSIER, MD,
ıd CHARLES WOOLEY, MD

**ıpravalvular aortic stenosis has a wide range of inical and morphologic expression. Since 1961, ; patients (aged 1 to 49 years) with documented ıpravalvular aortic stenosis have been evaluated. even (28%) had Williams' syndrome, 5 (20%) had familial form of supravalvular aortic stenosis, and 3 (52%) had a sporadic form. A blood pressure fference of >10 mm Hg between the arms was ted in 65% of the patients. Angiographically, 19 6%) had segmental supravalvular narrowing; 6 4%) had diffuse narrowing of the ascending rta.**

**Sixteen patients underwent patch aortoplasty. At ırgery, portions of the aortic valve cusps were equently attached to supravalvular tissue. This cusp tuck" resulted in distinctive angiographic atures and influenced the results of corrective ırgery. Three surgical deaths occurred in the early 960s—2 with diffuse narrowing of the aorta. Of the remaining 12 patients, followed for 1 to 12 years, 10 are asymptomatic, 1 has angina, and 1 died from cancer. All 8 patients who underwent postoperative catheterization had a thick band between the left and right coronary sinus which represented persistent attachment of portions of the aortic valve cusps to residual supravalvular tissue (cusp tuck). This resulted in aortic valvular gradients (23 to 48 mm Hg) in 4 patients and aortic valvular insufficiency in 2 patients. No significant supravalvular gradient was noted.**

**The 20-year experience with supravalvular aortic stenosis reported herein emphasizes a wide range of clinical and morphologic expression, the benefits and limitations of patch aortoplasty, and the importance of postoperative cardiac catheterization, and furthers the understanding of a complex clinical syndrome.**

ıpravalvular aortic stenosis is an unusual form of left ntricular outflow tract obstruction which has been cognized with increasing frequency during the last 30 ars. Little is known about the natural history and ng-term follow-up of this disorder. Since 1961, 25 ıtients with supravalvular aortic stenosis were evalıted at the Ohio State University Hospital and at the olumbus Children's Hospital. The present study reews our clinical, hemodynamic, angiographic, surgical, ıd follow-up experience with this group over the last ) years.

### Clinical Material

**Patient population:** Twenty-five patients with documented supravalvular aortic stenosis were included in this study, 15 male and 10 female. Their ages at the time of diagnosis ranged from 1 to 49 years (average 18). Twelve of the patients were 16 years or older at the time of diagnosis. Of the 25 patients, 15 are still followed up on a regular basis. Seven patients have died. Three patients were lost to follow-up immediately after an initial evaluation and cardiac catheterization.

Three clinical groups were recognized. A sporadic form occurred in 13 patients. These patients had normal growth and development and no family history of supravalvular aortic stenosis. Seven patients had Williams' syndrome, defined as entailing a characteristic elfin face and mental retardation associated with supravalvular aortic stenosis. The remaining 5 patients had a familial form in which a parent or a sibling had documented supravalvular aortic stenosis.

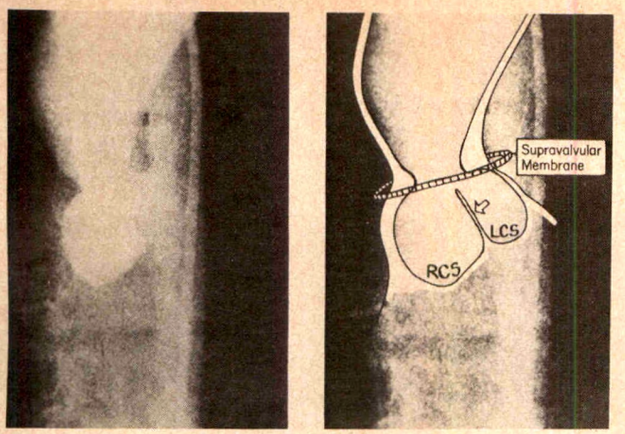

**FIGURE 1.** Aortic root injection in the anteroposterior projection demonstrating an hourglass form of supravalvular aortic stenosis. A band (**arrow**) is seen between the left (LCS) and right (RCA) coronary sinuses, extending to the supravalvular stenosis.

**Clinical evaluation:** All patients had an aortic systolic ejection murmur without an aortic valve ejection click. Blood pressure was recorded in both arms in 20 patients. Thirteen had a blood pressure difference of >10 mm Hg between the arms. In 11, blood pressure was higher in the right arm; in 2, the left arm had a higher reading.

The electrocardiogram showed left ventricular hypertrophy in 14, and a chest x-ray showed an enlarged heart in 9 of the 25 patients.

**Cardiac catheterization:** All patients had gradients between the left ventricle and the ascending aorta ranging from 7 to 170 mm Hg (average 88). The gradient was higher in the older age group, with an average gradient of 100 mm Hg in patients >16 years of age. Five patients had 2 cardiac catheterizations before surgery. Four had a progressive increase in gradient between the left ventricle and ascending aorta over a 4- to 12-year period, with the remaining patient's gradi unchanged over a 9-year period.

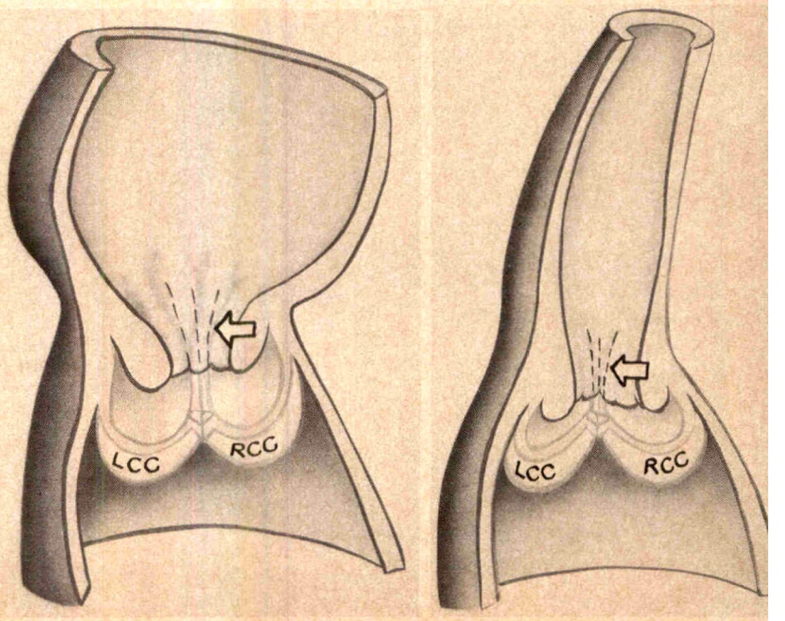
Angiographically, 2 types of supravalvular aortic sten were observed: an hourglass deformity and a hypoplastic ty In the hourglass deformity, seen in 19 of our patients, s mental narrowing of the ascending aorta just above the ao valve was noted. The aortic arch and descending aorta w of normal caliber. Six of our patients had the hypoplastic fo in which there was diffuse narrowing of the entire ascend aorta, aortic arch, and descending aorta.

In addition to the narrowing above the aortic valve, we a noted angiographic abnormalities in the aortic valve its Figure 1 is an aortic root angiogram in the anteroposter projection of an hourglass type of supravalvular aortic s nosis. A thick band exists between the right and left coron sinuses and was present in all preoperative angiograms. T band represents the apposition of the right and left ao valve cusps due to traction on the cusps by the supravalvu tissue. The band is a very important feature of supravalvu aortic stenosis and is discussed in detail later in this repo

Several associated cardiac lesions were noted. Two patie had angiographic evidence of severe peripheral pulmon artery stenosis. Two had a patent ductus arteriosus. Otl defects included subaortic membrane, atrial septal defe ventricular septal defect, mitral regurgitation, mitral va prolapse, and coarctation of the aorta.

**Follow-up: nonsurgical patients:** Nine patients have undergone surgery. Three have died: a 3-year-old boy fr Wilms' tumor, a 13-year-old girl suddenly after experienc syncope, and a 37-year-old male from subacute bacterial docarditis after resection of bowel cancer. Three other patie continue to be followed up: a teenaged girl who cannot u dergo an operation because of severe peripheral pulmon artery stenosis, a 34-year-old man with exertional chest p who refused surgery, and a 4-year-old boy who is awaiti surgery. Three patients were lost to follow-up after an init evaluation and cardiac catheterization.

**Follow-up: surgical patients:** Sixteen patients underw operative repair. Eleven surgical patients had an hourgl type of supravalvular aortic stenosis; 5 had a hypoplastic ao



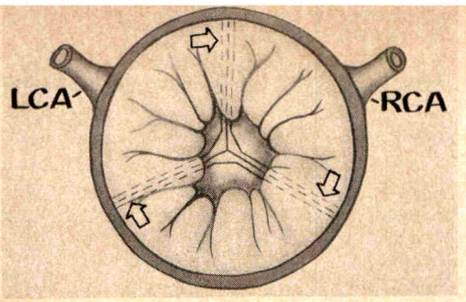


**FIGURE 2.** Hourglass (**left**) and hypoplastic (**right**) forms of supravalvular aortic stenosis. The **arrows** point to an area of apposition between the left coronary cusp (LCC) and right coronary cusp (RCC) which is tucked beneath the supravalvular stenosis.

ne left ventricular-aortic gradients ranged from 40 to 170 m Hg. At surgery, a lateral aortotomy was performed ex-nding across the supravalvular stenosis into the noncoronary sp. Figure 2 demonstrates the supravalvular constriction both the hourglass (left panel) and hypoplastic forms (right nel). The posterior wall of the aorta and the noncoronary sp were removed for illustrative purposes. Note that the left d right coronary cusps are tucked under the stenosing su-avalvular ring (arrows). This cusp tuck results in apposition the margins of these cusps, which is seen angiographically the thick band during diastole. This band was present in preoperative angiograms in patients with supravalvular rtic stenosis. Figure 3 is a cross-sectional view from above e supravalvular constriction. The left and right coronary teries are labeled. Portions of the aortic valve cusps and the rtic valve commissures are tucked under the supravalvular embrane, as depicted by the arrows. Surgical repair included tensive resection of the supravalvular obstruction and in-rtion of a Dacron patch over the aortotomy. Figure 4 shows e results after surgery. The patch effectively relieved the pravalvular obstruction and mobilized the noncoronary sp. However, persistent anterior supravalvular tissue re-ained with portions of the left and right aortic cusps tucked der this tissue (arrow).

The completed external repair is shown in Figure 5.

**Surgical results:** Thirteen surgical survivors have been llowed up for 1 month to 12 years. Eleven patients, aged 15 28 years, are currently asymptomatic. One patient with an

**GURE 4.** Postoperative cross-sectional view demonstrating portions

84 mm Hg gradient and normal coronary arteries underwent surgery at age 45. Exertional chest pain developed postoperatively. A stress thallium scan indicated an inferior perfusion defect immediately after exercise which resolved 4 hours later. Postoperative cardiac catheterization showed a reduction in gradient to 23 mm Hg. The right coronary artery could not be entered for selective injection and did not fill on aortic root injection, suggesting coronary ostial occlusion. Another patient who underwent surgery at age 49 had chest pain and shortness of breath postoperatively. She died from cancer at age 57.

There were 3 surgical deaths; all occurred in the early 1960s. Two of these patients had the hypoplastic form of supravalvular aortic stenosis.

Postoperative cardiac catheterization was performed in 8 patients 6 months to 12 years after surgery; all had reduction in the gradient between the left ventricle and aorta (Fig. 6). No significant supravalvular gradients were found. However, 4 patients had persistent gradients of 23 to 48 mm Hg at the

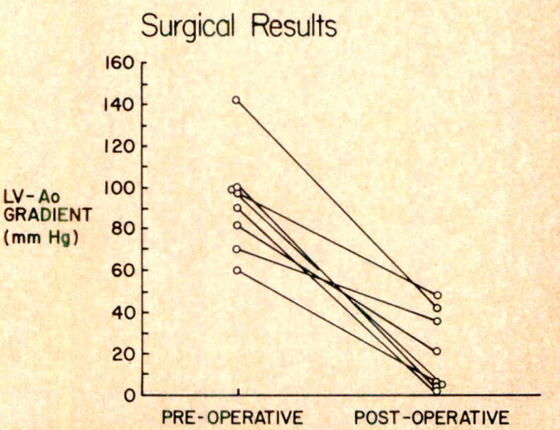

**FIGURE 6.** Pre- and postoperative gradients between the left ventricle

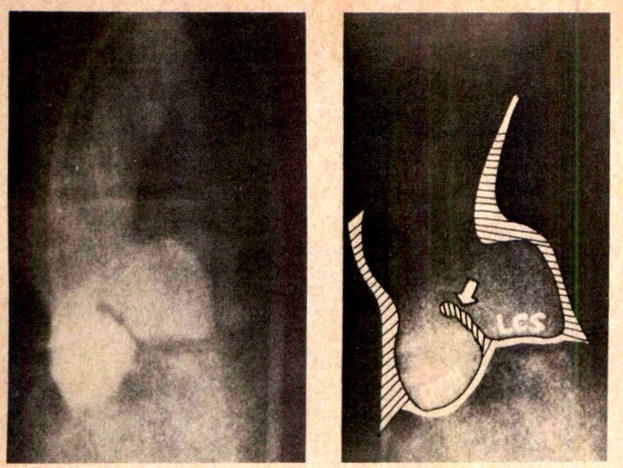

**FIGURE 7.** Postoperative aortic root angiogram in the anteroposterior projection demonstrating the thick band (**arrow**) between the right coronary sinus (RCS) and left coronary sinus (LCS). This patient had a 48 mm Hg gradient across the aortic valve but no supravalvular gradient.

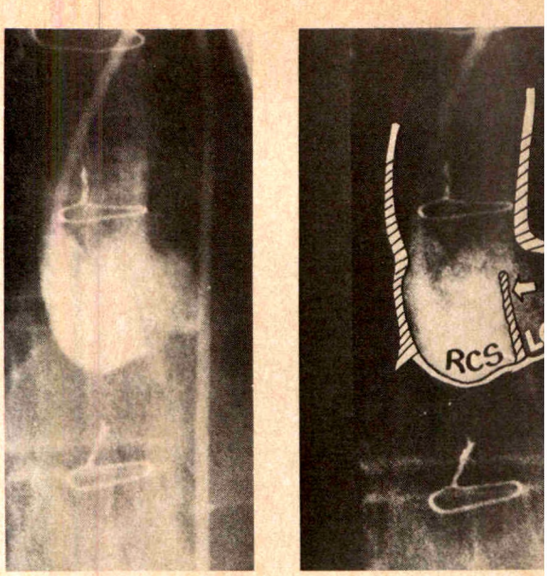

**FIGURE 8.** Postoperative aortic root angiogram in the anterop projection. The thick band is noted. This patient did not have a valve or a supravalvular gradient. LCS = left coronary sinus; right coronary sinus.

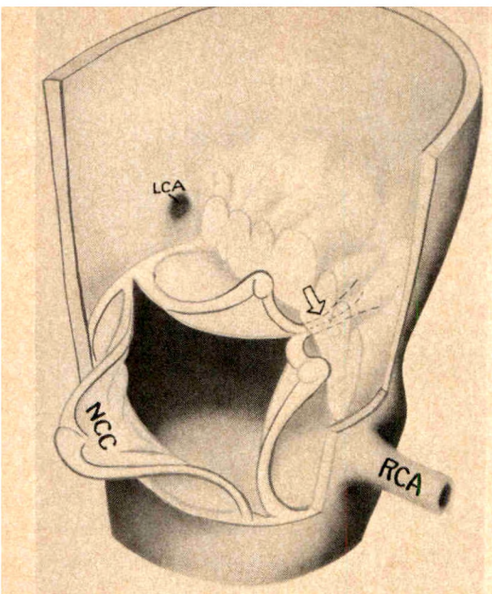
aortic valve level. Two of these patients had mild aortic insufficiency. All postoperative patients had a thick band between the right and left coronary sinuses, which was present preoperatively. This band was due to cusp tuck—the persistent attachment of portions of the aortic cusps to residual anterior supravalvular tissue. The band was present in all patients postoperatively, including those patients without a gradient between the left ventricle and aorta (Fig. 7 and 8).

## Discussion

Supravalvular aortic stenosis is a complex form of left ventricular outflow tract obstruction with distinctive morphologic features which influence the results of corrective surgery. Our study demonstrates that patch aortoplasty provides good postoperative results with asymptomatic patients for up to 12 years. However, residual abnormalities may remain, including gradients across the aortic valve and aortic valve insufficiency. These abnormalities appear related to the amount of attachment between the aortic valve cusps and residual anterior supravalvular tissue.



This attachment of the aortic valve leaflets to the supravalvular membrane—cusp tuck—has been recognized for years. In 1957, Cheu et al[1] described a crescent-shaped fibrous membrane above the aortic valve in a 37-year-old man. The right posterior aortic cusps were attached to the undersurface of the membrane. One year later, Burry[2] noted commissural fusion with a supravalvular ridge in a patient with morphologic features of Marfan's syndrome. Denie and Verheught[3] described a 25-year-old patient with angina who had fusion between all 3 aortic cusps at the very outer edge near the commissures. The left coronary artery originated from a blind pouch which was formed from the free margin of the left aortic cusp with the aortic wall. This pouch communicated with the free aortic lumen by a very narrow opening. Edwards,[4] in his classification of the pathology of supravalvular aortic stenosis, mentioned that up to one fourth of the cases have associated changes of the aortic valve cusps, most notably sions of portions of the cusps to the supravalvul nosis.

As surgical techniques improved, it became important to differentiate supravalvular aortic st from other forms of outflow tract obstruction. W viously emphasized the familial predisposition disorder, the clinical significance of the blood pr difference in the arms, and the attachment of the cusps to the supravalvular tissue.[5]

Patch aortoplasty has been the surgical proced choice for supravalvular aortic stenosis; howev modynamic abnormalities have been noted in p erative studies. Rastelli et al[6] observed that gra persisted after patch aortoplasty in 14 of 16 pa but the site of the gradient was not mentioned. et al[7] studied 6 patients postoperatively and did n a supravalvular gradient, but recorded pressu ferences between the left ventricle and aorta cons with valvular or possibly subvalvular stenosis. et al[8] found residual gradients in 5 postoperati tients, 2 of which occurred at the valvular level.

Doty et al[9] pointed out that patch aortoplasty in an asymmetric surgical repair and occasionall not relieve outflow tract obstruction. They desig symmetric form of reconstruction in which the ste supravalvular ring is divided at 2 points, all lengthening of 2 aortic cusps with better valve fur A reduction in the gradient between the left ve and the aorta was noted on intraoperative me ments; however, postoperative cardiac catheteriz were not reported. This type of repair may be n in some cases with marked fusion of the coronary to the supravalvular tissue.

There may be other reasons for valvular gra after surgical repair. Thirty % of aortic valves

**RE 9.** Artist's depiction of persistent attachment of portions of the valve (**arrow**) to residual anterior supravalvular tissue which has partly resected. The noncoronary cusp (NCC) has been mobilized e Dacron patch (not shown), which is inserted posteriorly. LCA = oronary artery; RCA = right coronary artery.

ed to be thickened in patients with supravalvular ic stenosis. Cheevers, in the original description of avalvular aortic stenosis, noted that the aortic valve be calcified; hence, valvular gradients may be due ntrinsic valvular disease.[10] Patients with a combi- on of supravalvular aortic stenosis and intrinsic ic valve disease represent a more complex form of disease, and patch aortoplasty combined with val- tomy or aortic valve replacement may be necessary chieve satisfactory results.

he results of this study show that patch aortoplasty fective in reducing supravalvular obstruction but portions of the aortic valve remain attached to re- al anterior supravalvular membrane (Fig. 9). This tuck causes traction on the aortic valve leaflets and osition of the valve margins, which has the angio- hic appearance of a thick band between the right left coronary cusps (Fig. 7 and 8). This results in ic valvular abnormalities manifested by persistent lients across the aortic valve with or without aortic e insufficiency.

valvular gradient was operated on 12 years ago. The patients operated on within the last few years have minimal, if any, aortic valvular gradients despite angiographic evidence of cusp tuck. Whether there is progressive aortic valve dysfunction due to the persistent attachment of the anterior portions of the aortic valve to the residual anterior supravalvular membrane or whether surgery has improved with more aggressive resection of the anterior tissue is not known at this time. Serial catheterizations, precise intraoperative observations, and detailed pathologic examinations will be needed to provide more information.

*In summary*, our 20-year experience with supravalvular aortic stenosis demonstrates a wide range of clinical features which allow differentiation from other forms of left ventricular outflow tract obstruction. Attachment between the supravalvular tissue and portions of the aortic valve—cusp tuck—causes distinctive angiographic abnormalities and influences the results of corrective surgery. Patch aortoplasty for supravalvular aortic stenosis produces good clinical results and a reduction in the pressure difference between the left ventricle and ascending aorta. However, residual valvular abnormalities remain, including aortic stenosis and aortic insufficiency. These abnormalities need to be recognized to assist in the long-term management of these patients.

# Radionuclide Stroke Count Ratios for Assessment of Right And Left Ventricular Volume Overload in Children

MARK D. PARRISH, MD, THOMAS P. GRAHAM, Jr., MD, MARK L. BORN, MD, JEROME P. JONES, PhD, ROBERT J. BOUCEK, Jr., MD, MICHAEL ARTMAN, MD, and C. LEON PARTAIN, MD, PhD

**The ratio of left ventricular to right ventricular stroke counts measured by radionuclide angiography has been used in adults to estimate the severity of left-sided valvular regurgitation. The validation of this technique in children for assessment of right and left ventricular volume overload is reported herein. Radionuclide stroke count ratios in 60 children aged 0.5 to 19 years (mean 11) were determined. Based on their diagnoses, the patients were divided into 3 groups: (1) normal—40 patients with no shunts or valvular regurgitation, (2) left ventricular volume overload—13 patients with mitral or aortic regurgitation, or both, and (3) right ventricular volume overload—7 patients, 2 with severe tricuspid regurgitation, 3 with atrial septal defects, and 2 with total anomalous pulmonary venous drainage. The radionuclide stroke count ratio clearly differentiated these groups ($p < 0.05$): normal patients had a stroke count ratio of 1.04 ± 0.17 (mean ± 1 standard deviation), the left ventricular volume overload group had a stroke count ratio of 2.43 ± 0.86, and the right ventricular volume overload group had a stroke count ratio of 0.44 ± 0.17. In 22 of our 60 patients, radionuclide stroke count ratios were compared with cineangiographic stroke volume ratios, resulting in a correlation coefficient of 0.88. It is concluded that radionuclide ventriculography is an excellent tool for qualitative and quantitative assessment of valvular regurgitation in children.**

The ratio of the left ventricular stroke output to right ventricular stroke output (stroke volume ratio) provides an index of left ventricular volume overload in patients with aortic or mitral regurgitation.[1–6] This ratio has been estimated noninvasively in adults with radionuclide ventriculography.[3–6] However, the use of this radionuclide technique in assessing right ventricular volume overload in children is unknown. For these reasons, we now report our experience with the radionuclide stroke count ratio in children for the assessment of right and left ventricular volume overload. The radionuclide stroke count ratio is validated by comparison with the cineangiographic stroke volume ratio.

## Methods

From June 1980 to August 1981, we obtained equilibrium radionuclide ventriculograms in 88 children. Twenty-eight of these patients were excluded from the study for the following reasons: (1) inadequate blood pool labeling, septal definition, or both (6 patients); (2) single ventricle anatomy (5 patients); and (3) bidirectional shunts, regurgitant lesions, or both, affecting both ventricles (17 patients). The remainder of our patients (60 children) were included in this study. These children were assigned to 1 of 3 categories based on clinical and catheterization findings: (1) Normal—40 children were assigned to this category because they had no shunts or valvular regurgitation. (2) Left ventricular volume overload—13 children were assigned to this category based on clinical and catheterization findings of aortic or mitral regurgitation. (3) Right ventricular volume overload—7 children were assigned to this category based on clinical and catheterization findings of tricuspid regurgitation, atrial septal defect, or total anomalous pulmonary venous drainage.

Table I further characterizes our patients. The diagnoses are diverse, with most children in the normal group having postoperative repair of cardiac defects (tetralogy of Fallot,

ransposition of the great arteries, and atrial septal defect). e right and left ventricular volume overload groups were nprised of patients who had not undergone previous sury. Although we had a few 19-year-old patients, the mean for the total group of 60 children was 11 ± 4.9 years (mean tandard deviation).

Multiple-gated equilibrium radionuclide studies were formed for diagnostic purposes in all patients. Informed nsent was obtained before performing these studies. Diagtic cardiac catheterizations were done in 22 of our 60 pants within 1 week of the radionuclide study, allowing ranuclide-cineangiographic correlations.

Standard techniques were used for collection of radionule studies, with in vivo labeling of red blood cells using an ult dose of 20 mCi, adjusted downward for children based their body surface area.[7,8] We have previously described collection and analysis methods.[9] Right and left ventricr regions at end-diastole and end-systole were identified hand using criteria similar to that described by Maddahi l.[10] The following formula was used to calculate the stroke nts: Ventricular stroke counts = (end-diastolic counts − kground counts) − (end-systolic counts − background nts). The ratio of left ventricular stroke counts to right tricular stroke counts was then determined for each ge.

From cineangiograms, right and left ventricular stroke ume ratios were determined using previously published thods. Volumes were calculated from biplane images for patients, using the area-length method for the left ventri-[11] and Simpson's rule for the right ventricle.[12] The ratio of left ventricular to right ventricular stroke volume was then culated.

Radionuclide ventricular stroke count ratios were determed in 5 patients by 1 observer on 2 different occasions to ess intraobserver variability. In addition, a second observer ependently performed the region identification for the e 5 patients (interobserver variability). All observers were blinded to each other's results as well as to the cineangiographic results.

Stroke count ratios from the radionuclide images were statistically compared to cineangiographic stroke volume ratios using linear regression analysis. Intraobserver and interobserver variation was assessed by calculating the absolute difference between observer 1's first determination, and each subsequent determination (observer 1's second determination and observer 2's determination). These absolute differences for each patient were then expressed as a percentage of observer 1's first determination. The mean values for stroke count ratios in each of our 3 patient groups were compared by 1-way analysis of variance followed by Student-Neuman-Keul's test. The level of statistical significance was chosen as $p < 0.05$.

## Results

Assessment of intra- and interobserver variability in the determination of radionuclide stroke count ratios disclosed differences of 24 ± 14% and 32 ± 19%, respectively. Despite this variability, we demonstrated a good correlation between radionuclide studies and cineangiographic studies. Figure 1 shows the radionuclide cineangiographic comparison (r = 0.88). The radionuclide technique generally overestimated the actual (cineangiographic) stroke volume ratio (radionuclide

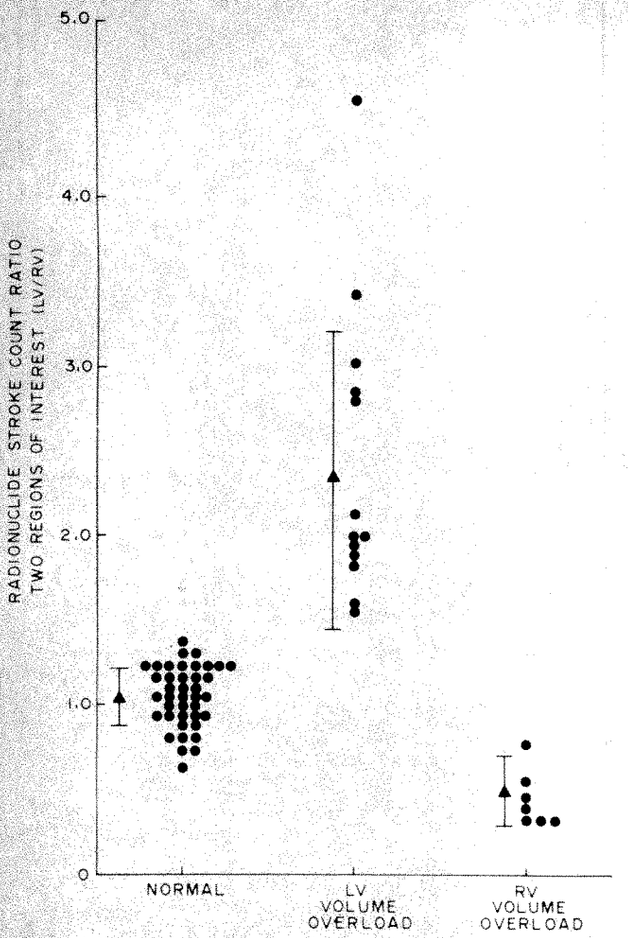

**FIGURE 2.** Radionuclide stroke count ratios in our 3 patient groups. **Error bars** encompass 1 standard deviation above and below the mean. **Circles** represent individual values, **triangles** mean values. LV = left ventricle; RV = right ventricle.

stroke count ratio = 1.6 × cineangiographic stroke volume ratio − 0.49) (Fig. 1).

Figure 2 shows the radionuclide stroke count ratios for our 3 patient groups. The mean stroke count ratio for the normal group was 1.04 ± 0.17 (mean ± standard deviation). The mean stroke count ratio for the left ventricular volume overload group (2.43 ± 0.86) was significantly greater than the normal group ($p < 0.05$). Furthermore, the mean stroke count ratio for the right ventricular volume overload group (0.44 ± 0.17) was significantly less than for the normal group ($p < 0.05$).

Table II summarizes the normal range for radionuclide stroke counts. From the data in Figure 2, we defined a normal stroke count ratio as ranging from 0.70 to 1.38 (2 standard deviations below and above the mean). Only 1 of the 40 normal patients fell outside this range. This patient had had Mustard repair of D-transposition of the great vessels, and had a radionuclide stroke count ratio of 0.62. The right ventricular-right atrial border was difficult to define on the radionuclide image in this patient and may have led to inaccuracy in the estimation of the stroke count ratio.

**TABLE II Radionuclide Stroke Count Ratios**

| Groups | Patients Outside Normal Range* | Patients Within Normal Range* |
|---|---|---|
| Normal | 1/40 | 39/40 |
| LV volume overload | 13/13 | 0/13 |
| RV volume overload | 6/7 | 1/7 |

* Normal range 0.70 to 1.38 (2 standard deviations to either side of the mean). LV = left ventricle; RV = right ventricle.

All patients in the left ventricular volume overload group had radionuclide stroke count ratios >1.38. In 1 patient from this group, the cineangiographic stroke volume ratio was 1.0 despite the subjective impression from the left ventricular angiogram of moderate mitral regurgitation and a large left atrium. The radionuclide stroke count ratio was 1.56, leading us to question the accuracy of the cineangiography determined stroke volume ratio in this particular patient.

Only 1 of the 7 patients with right ventricular volume overload had a radionuclide stroke count ratio within the normal range (0.77). This patient had total anomalous pulmonary venous drainage.

## Discussion

Both echocardiography and nuclear angiography have been used extensively for the evaluation of cardiac size and function in patients with left-sided valvular regurgitation.[13–17] However, only recently have there been attempts to actually quantitate the severity of valvular regurgitation by noninvasive techniques. Bommer et al[18] found that pulsed Doppler 2-dimensional echocardiography can be used to quantitate aortic regurgitation. In addition, several workers[6,19–21] have validated the equilibrium radionuclide technique for quantitation of valvular regurgitation, finding radionuclide-cineangiographic correlation coefficients of 0.72 to 0.95. This radionuclide technique estimates right and left ventricular stroke volumes by measuring the change in regional counts from end-diastole to end-systole. The severity of valvular regurgitation is then assessed by calculating a regurgitant index (left ventricular stroke counts divided by right ventricular stroke counts).

The previous work with radionuclide assessment of valvular regurgitation has been limited entirely to adult patients with left-sided valvular regurgitation. We now report our validation of this technique in children. In addition, we have used this method to evaluate several patients with right-sided volume overload.

Several potential methodologic problems and sources of error are inherent in this radionuclide technique. The major difficulty centers around the appropriate identification of the ventricular regions of interest. Adequate septal visualization must be obtained in order to separate and identify each ventricle. Variable red blood cell labeling, motion artifact, and unusual ventricular geometry and position in children with congenital heart disease can make septal identification more difficult than in adult patients. Six patients with inadequate septal visualization were excluded from this study.

Separation of ventricular from atrial activity may be difficult with the equilibrium radionuclide technique. This problem is of additional concern in the current study, because some diseases we are interested in evaluating (tricuspid and mitral regurgitation) may increase right or left atrial size and thus increase overlap of atrial and ventricular activity. If atrial overlap is greatest on the end-systolic image, this error would tend to decrease the estimated stroke counts for the affected ventricle, resulting in an underestimation of the severity of valvular regurgitation. In our patients, we attempted to improve atrial-ventricular separation by collecting studies from a left anterior oblique view with 5 to 15° caudal tilt. Careful study of playback images was also quite helpful in identifying the atrial ventricular border. We do not believe that there was any systematic error in the estimation of the stroke counts from right or left ventricle, because the normal group had a mean stroke count ratio near unity (1.04). There is, however, a moderate degree of intra- and interobserver variability in this measurement, which may reflect the multiple regions of interest one must identify in order to derive the stroke count ratio.

Lam et al[22] validated stroke count ratios in normal patients and those with left-sided volume overload. They found discordant radionuclide-cineangiographic results in 12 of 100 patients, and correlated this discrepancy with severe left ventricular dysfunction or mitral valve prolapse. We found discrepant results in 2 patients (Table II). One of these patients had had Mustard repair of D-transposition and had a radionuclide stroke count ratio of 0.62, despite clinical and catheterization findings indicating no significant shunt or valvular insufficiency. No distinct atrial-ventricular disorder could be appreciated in this patient, and we hypothesize that atrial activity overlapped with the left ventricle, reducing the stroke count ratio. Five other patients with D-transposition and poor atrial separation had stroke count ratios within the normal range. The second patient with discordant results had total anomalous pulmonary venous drainage. Although the radionuclide stroke count ratio was 0.77, it was within the normal range. A large portion of right atrial activity in this patient may have been included in the right ventricular end-systolic frame and excluded from the end-diastolic frame, artificially increasing the stroke count ratio. We had 1 patient with mitral valve prolapse, and 5 patients with severe cardiomyopathy. Radionuclide, catheterization, and clinical findings were in agreement in these patients.

Despite these methodologic considerations, we found good correlation between radionuclide and cineangiographic estimates of the stroke volume ratio ($r = .88$). Furthermore, the radionuclide technique clearly identified and separated patients with left ventricular volume overload from patients with no volume overload. Severe right ventricular volume overload could also be detected in 6 of 7 patients. We have not attempted to evaluate children with volume overload of both ventricles. In this situation, the radionuclide technique might provide an indication of which ventricle was more severely overloaded.

We conclude that the equilibrium radionuclide technique provides a useful noninvasive tool for qualitative and quantitative assessment of right and left ventricular volume overload in children with congenital heart disease.

# Pulmonary Vascular Disease in Secundum Atrial Septal Defect in Childhood

SHEILA G. HAWORTH, MD, FRCP

**Pulmonary vascular structure was analyzed in the lungs of 10 patients with a secundum atrial septal defect (ASD) in whom pulmonary hypertension had developed. Four patients were aged 6 months or less, 5 were aged 2 to 9 years, and 1 was 21 years old. Pulmonary vascular structure was analyzed using lung biopsy tissue in 5 and autopsy material in the other 5. All the infants presented with heart failure and all had a marked increase in pulmonary arterial smooth muscle; only 1 infant survived surgery. Of the 5 older children, 1 presented with cyanosis, but in the rest the ASD was incidental to the presentation. Three patients had severe pulmonary vascular disease, similar to that seen in adults with a hypertensive ASD. Only 2 older children underwent successful surgery. In 1 child and in the 1 adult, the severity of the pulmonary vascular disease precluded surgery. The ASD was closed in 8 patients, but only 3 survived. Pulmonary hypertension develops rarely in secundum ASD in childhood.**

Most children with a secundum ASD are asymptomatic. Rarely, cardiac failure develops in young children; in such cases the severity of pulmonary hypertension is frequently greater than that found in the asymptomatic older child.[1–4] Conservative management may not be successful and the operative mortality is greater than in older children with an ASD.[2] In the pulmonary circulation, the structural changes found in older patients are usually restricted to medial hypertrophy and slight intimal proliferation, although plexiform lesions can occur in the presence of severe pulmonary hypertension.[5] To understand the structural basis of pulmonary hypertension in ASD and its relation to age, the clinical findings and pulmonary vascular changes were studied in 10 patients aged 3.5 months to 21 years.

## Methods

Six male and 4 female patients were studied (Table I). Six patients presented during the first 6 months of life and all except Patient 7 had signs of congestive heart failure and failure to thrive (Table I). Patient 1 was cyanotic when he presented at 6 weeks of age. All had an ejection systolic murmur at the left sternal border, and in all except Case 7 the pulmonary component of the second heart sound was accentuated. Patient 6 also had the soft continuous murmur of a small patent ductus arteriosus in the left infraclavicular region. The remaining 4 patients presented between 2 and 16 years of age. Patient 5 presented with cyanosis at 2 years, but in the other patients the presence of an ASD was incidental. All these older patients had an ejection systolic murmur in the pulmonary area and wide splitting of the second heart sound with accentuation of the pulmonary component, but only 2 had an rsR′ pattern in the right precordial leads of the electrocardiogram. In all 10 patients the electrocardiogram showed sinus rhythm with right ventricular hypertrophy. The chest radiogram showed slight cardiac enlargement with pulmonary plethora in all except Cases 5, 7, and 10. In Cases 5 and 10, the proximal pulmonary arteries appeared dilated with pruning of the peripheral arteries.

All patients underwent a cardiac catheterization study except Patient 9, in whom the diagnosis was established by 2-D echocardiography (Table II). All patients had pulmonary hypertension, but this was most severe in the 5 patients catheterized during the first 2 years of life and in the 19-year-old man. Case 9 had significant pulmonary hypertension after closure of the ASD. In all except Case 10 there was a left-to-right shunt at the atrial level with a pulmonary: systemic flow ratio of 1.3 to 3.3:1. Pulmonary arteriolar resistance was 4 to 16 units/$m^2$.

An open lung biopsy was performed in 5 patients, immediately after the cardiac catheterization study in 2 patients, 2 years after the study in Patient 10, and at operation in the remaining 2 patients (Table I).

The 5 symptomatic infants were given intensive medical treatment, but only Patient 6 responded satisfactorily. For the entire group, the ASD was closed in 8 patients. The time between presentation and operation was <6 months except in Cases 6 and 7. The ASD was closed successfully in only 3 children aged 7 months, 7 years, and 9 years. Five children died at or soon after operation. The 2 remaining patients did not undergo surgical treatment because the lung biopsy showed severe obliterative pulmonary vascular disease.

A = uninjected autopsy material; A+I = uninjected and injected autopsy material; B = biopsy; CF = cardiac failure; FT = failure to thrive; RTI = respiratory tract infections.

No patient had coarctation of the aorta and none had an obstructive left heart abnormality. The mitral valve was normal at autopsy in 5 cases and at operation in 3. In the remaining 2 cases, there was no auscultatory evidence of mitral valve dysfunction; left ventricular cineangiography was normal in both.

Thus, in 8 patients an isolated secundum ASD was the only congenital malformation of the heart or great vessels and in the remaining 2 patients it was the only significant malformation.

**Pathologic preparation and examination:** The lung tissue examined was obtained by biopsy in 5 cases and at autopsy in the remaining 5 (Table I). Uninjected tissue was analyzed using quantitative morphometric techniques in all 10 cases. In 2 of the autopsied cases, a piece of lung tissue was removed from the specimen and the pulmonary arteries were then injected with a barium-sulfate gelatin mixture; in these cases, both injected and uninjected tissue was analyzed.[6,7] The lungs of the 2 injected specimens were radiographed, and on the arteriograms the lumen diameter of the preacinar arteries was measured at 25% intervals along the pathway from hilus to pleural surface. Paraffin-embedded 4 $\mu$m sections were stained with Miller's elastic stain, with hematoxylin and eosin, and with Perls' stain for iron. In the injected specimen of Case 5, the artery of the anterior segment of the left upper lobe was reconstructed from hilus to pleural surface by analysis of step and serial sections. Microscopically, the following features of peripheral arterial structure were studied: (1) The external diameter and medial thickness was measured in approximately 100 vessels in each injected specimen and in all the arteries present in a biopsy specimen, and the percent arterial medial thickness was calculated for each vessel: Percent arterial medial thickness = (2 × wall thickness/external diameter) ×100. The arteries were then divided into size ranges and the mean percent medial thickness was calculated for each size range. (2) Where a small artery accompanies a small airway it can be characterized by reference to the type of airway it accompanies. In each uninjected specimen, the structure of the arterial wall, whether muscular, partly muscular, or nonmuscular, was described at each airway level; in this way the degree of extension of muscle along the arterial pathway was established. Also, the external diameter of all arteries at each airway level was measured and the mean calculated. (3) The number of arteries and alveoli were counted in the same area of lung section and the result expressed as a ratio: this made allowance for any difference in the degree of inflation in various lungs. (4) A qualitative assessment of the appearance of the arteries at each airway level was made.

* Calculations unreliable due to pulmonary venous desaturation. † Rp decreased to 8 units/m$^2$ on inhalation of 100% oxygen. This was the only patient in whom pulmonary blood flow was measured. LV = left ventricular; PA = pulmonary arterial; RA = right atrial; Rp = pulmonary arteriolar resistance.

Normal data on uninjected lung tissue was obtained by analyzing postmortem material from 13 children who died without cardiopulmonary disease at 3 months to 9 years of age. Mean percent arterial medial thickness did not differ significantly in children of different ages, and therefore for this assessment the results were pooled. The mean external diameter and the proportion of nonmuscularized, partly muscularized, and entirely muscularized arteries accompanying each type of peripheral airway was determined in 9 normal cases and the alveolar-arterial ratio in 7.

## Results

**Arteriograms:** In Patient 4, aged 6 months, the lumen diameter of the preacinar arteries was increased from the hilus to the pleural surface and was greater than is normal at 2 years of age. The subsegmental and more peripheral arteries were tortuous. The background haze of small arteries was normal. By contrast, in Patient 5, aged 2 years, the arteries were smaller than is normal at 10 months of age. The peripheral arteries were tortuous and many anastomoses between the pulmonary arteries were seen at the pleural surface. An abnormal, fluffy haze surrounded each subsegmental artery and there were intervening zones without a haze, suggesting failure of small lateral branches to fill with contrast material.

### Qualitative Assessment

**Arterial wall structure:** The microscopic appearance of the pulmonary arteries was similar in the 4 patients aged 3 to 6 months (Cases 1 to 4), and consisted of an increase in muscularity of both pre- and intraacinar arteries. The normally muscularized preacinar, terminal, and respiratory bronchiolar arteries showed an increase in wall thickness, and muscle was present in more peripheral arteries than normal—in arteries accompanying alveolar ducts and lying within the alveolar walls (Fig. 1). Intimal proliferation was seen in several respiratory bronchiolar arteries in Case 2.

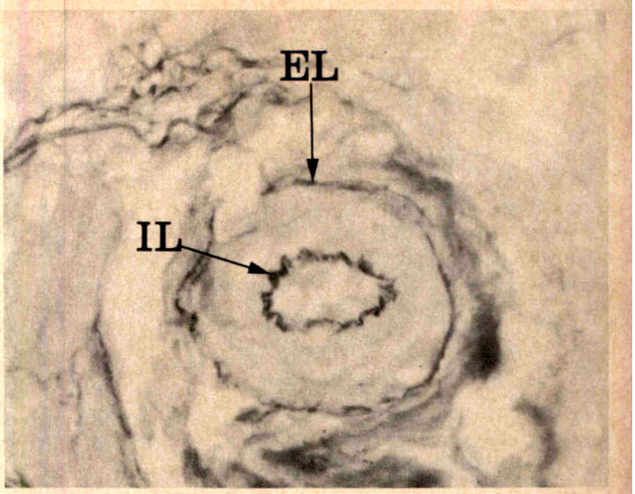

**FIGURE 1.** Photomicrograph of an artery accompanying an alveolar duct in Case 1, showing a thick media lying between internal (IL) and external (EL) elastic laminae. (Magnification ×982, reduced 22%.) Stain for this and subsequent photomicrographs: Miller's elastic stain counterstained with van Gieson's stain.

In the 6 older children, the structural changes were less uniform. Changes were least severe in Cases 6 and 8.

In Patient 5, severe pulmonary vascular disease was present at 2 years of age. In random and serial sections muscular preacinar arteries with intimal proliferation and fibrosis gave rise to dilated, thin-walled saccular branches whose lumens were almost obstructed by intimal proliferation at origin from the parent branches (Fig. 2, left). Terminal and respiratory bronchiolar ar-

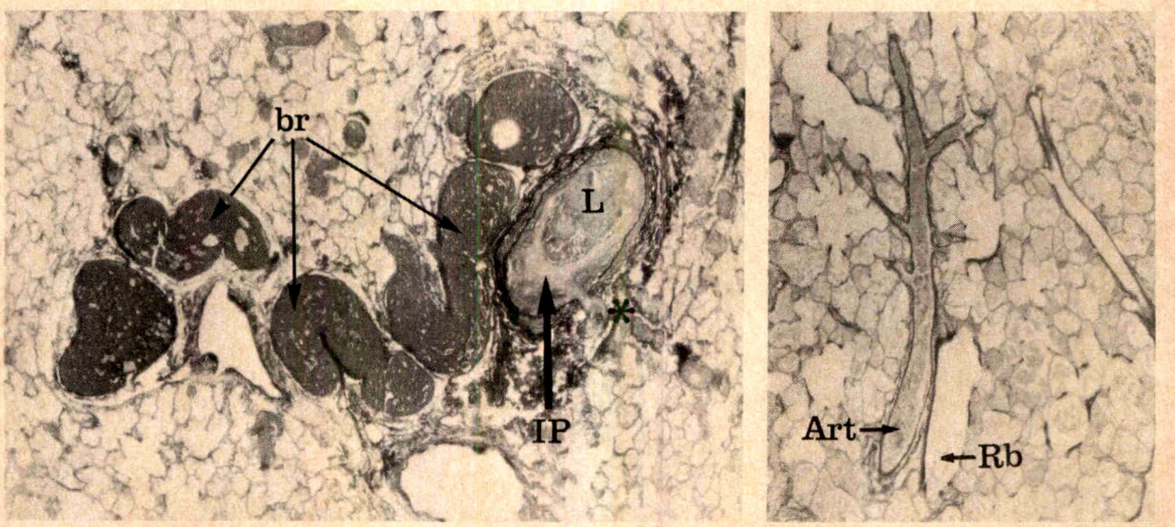

**FIGURE 2.** Photomicrographs of 2 sections of a serial reconstruction of the injected pulmonary artery to the anterior segment of the left upper lobe in Case 5. **Left,** a preacinar artery, with a lumen (L) narrowed by intimal proliferation and thin-walled branches (br). One branch (**asterisk**) is obstructed at its origin by intimal proliferation (IP). **Right,** the preacinar artery on the **left** has become a thin-walled artery (Art) accompanying a respiratory bronchiolus (Rb). (Magnifications ×61.7, reduced 36%.)

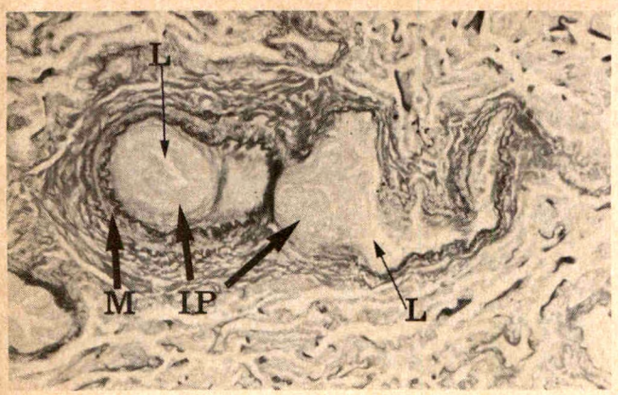

**FIGURE 3.** Photomicrograph of a small preacinar artery in Case 7, showing narrowing of the lumen (L) by intimal proliferation (IP). M = media. (Magnification ×216, reduced 40%.)

teries contained only a thin layer of muscle cells (Fig. 2, right). The more peripheral alveolar duct and alveolar wall arteries did not generally contain muscle and appeared fragile, dilated, and thin-walled. The lumens of a few intraacinar arteries were obliterated by intimal fibrosis.

Three of the older patients (Cases 7, 9, and 10) also had changes of severe pulmonary vascular disease. Intimal fibrosis occurred more frequently than in Case 5 and was more severe the older the child.

In Case 7, the preacinar arteries were abnormally thick-walled and many branches were occluded at their origin by concentric intimal proliferation (Fig. 3). Terminal and respiratory bronchiolar and alveolar duct arteries showed medial atrophy and, unlike in Case 5, intimal proliferation and fibrosis occluded the lumens of many of these small vessels. Within the alveolar walls some arteries were occluded by fibrosis while others showed medial atrophy and dilatation.

The changes were similar in Case 9, but less severe (Fig. 4). In Patient 10, aged 21 years, the picture differed from that seen in the children because of the greater atrophy of the media in large preacinar and intraacinar arteries, and in the greater severity of intimal fibrosis. Elastosis, a thickening of internal and external elastic laminae and increase in elastic fibers within the media, was severe. The media was fibrotic in some arteries, with collagen appearing between the muscle cells and elastic fibers. In Cases 5, 7, 9, and 10 the adventitia was abnormally thick and the collagen appeared dense.

**Vein wall structure:** In 4 patients aged 2 years or more (Cases 5, 6, 7, and 10) the veins were abnormally thick-walled and the small veins were "arterialized." Intimal fibrosis occurred in Cases 6 and 10 and was severe in the latter. In 1 infant, Patient 3, vein wall thickness was slightly increased.

Siderophages were scattered in clumps throughout the sections of tissue in Cases 7 and 10, with some deposition of iron in the arterial walls.

### Quantitative Assessment

**Percent arterial medial thickness:** *Uninjected material:* In patients 1 to 4, aged 3 to 6 months, percent arterial medial thickness was greater than normal in arteries of all sizes (Fig. 5). Of the 6 older children, in 3 (Cases 6, 7, and 9) muscularity was greater than normal in arteries <450 μm in diameter, but was below that seen in the 4 younger children with an ASD (Fig. 6). In Case 8 the percent medial thickness was normal. In Case 10, muscle was greater than normal in arteries of ≥250 μm, and the normal percent arterial medial thickness in the smaller arteries was associated with the appearance of medial atrophy. In Case 5, the percent medial thickness in arteries <700 μm in diameter was high and similar to that seen in the 4 younger cases, but was below normal in arteries <350 μm in diameter.

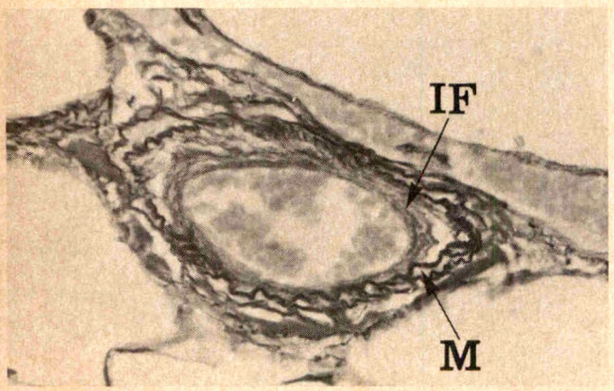

**FIGURE 4.** Photomicrograph of a respiratory bronchiolar artery in Case 9, showing a layer of intimal fibrosis (IF) within the media (M). (Magnification ×540, reduced 37%.)

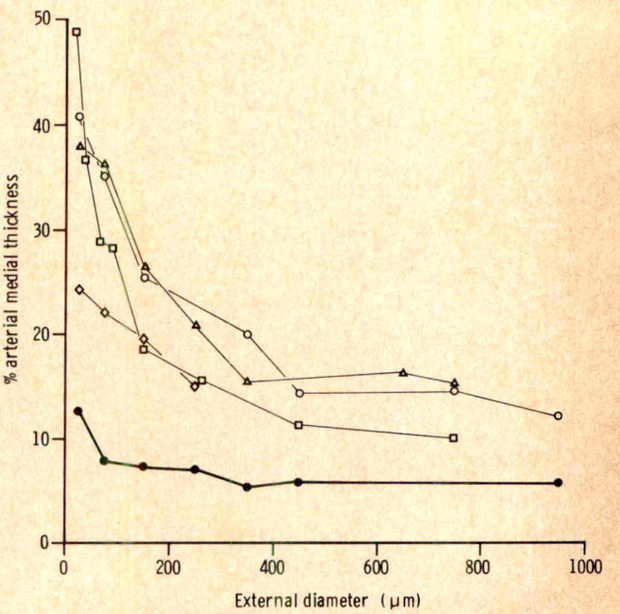

**FIGURE 5.** Mean percent arterial medial thickness related to external diameter (μm) in uninjected tissue from 4 infants, showing a considerable increase in muscularity above the normal level. **Open circles** indicate Case 1; **diamonds,** Case 2; **squares,** Case 3; **triangles,** Case 4; **closed circles,** normal, 3 months to 9 years.

*Injected material:* The more precise measurements of the percent arterial medial thickness made on the injected lung tissue from Cases 4 and 5 confirmed the observations made on the uninjected tissue (Fig. 7).

**Structure of arteries accompanying peripheral airways:** In the 4 youngest patients (Cases 1 to 4) the proportion of partially muscularized and muscularized arteries at alveolar duct and alveolar wall level was greater than normal. In the normal child of similar age, the proportion of entirely muscularized alveolar duct arteries is <60% and it is unusual to find many muscularized arteries within the alveolar wall. In these 4 infants, 64 to 100% of alveolar duct arteries were entirely muscularized and 40 to 100% of alveolar wall arteries contained muscle cells. Of the 6 older patients, the proportion of partly muscularized alveolar wall arteries was increased in Case 7 at the expense of nonmuscularized vessels, from a normal value of approximately 60% to 80%. Muscularization was most severe in Case 9, where almost half the alveolar wall arteries were entirely surrounded by a coat of muscle cells. Cases 5 and 10 showed a reduction in the proportion of partly muscularized and muscularized arteries at the respiratory bronchiolar, alveolar duct, and alveolar wall level; in Case 10 this was due to medial atrophy. There was no abnormal extension of muscle in Cases 6 and 8.

**Size and number of intraacinar arteries:** In 6 cases, the mean external diameter of intraacinar arteries was normal for age (Table III). Only in Case 4 were the arteries larger than normal; in this instance the luminal diameter of the preacinar arteries was also greater than normal on the postmortem arteriogram. The arteries were smaller than normal in Cases 6, 7, and 10; in all these 3, aged 5, 5, and 21 years, respectively, the arteries were similar to the normal at <2 years of age. In Case 10, intimal fibrosis was severe and many arteries appeared shrunken and fibrotic.

The alveolar/arterial ratio was determined in 7 cases (Table III). It was not possible to determine the ratio in Case 7 because the alveoli were not well expanded and in Cases 5 and 10 many alveolar wall arteries were either occluded by fibrotic change or replaced by thin-walled dilated arteries or both. The ratio was markedly increased in Cases 1 and 2, suggesting a reduction in the number of intraacinar arteries, and slightly increased in Case 9. The alveolar/arterial ratio was normal in the remaining 4 cases.

**Relation to the Heath and Edwards Classification of pulmonary vascular disease:** Had the Heath and Edwards Classification[8] been used, the pulmonary vascular changes in the 4 infants would have been classified as grade I at all levels along the arterial pathway. Using the modification of the Heath and Edwards Classification proposed by Rabinovitch et al,[9] the changes in Cases 3 and 4, extension of muscle into more peripheral arteries than normal plus medial hypertrophy in normally muscularized arteries, indicated grade Ib disease. In addition to both these changes, Cases 1 and 2 also had a reduction in intraacinar arterial number, indicating grade Ic disease.

Of the 6 older children, Cases 6 and 8 showed only grade I pulmonary vascular disease. In Cases 5, 7, and

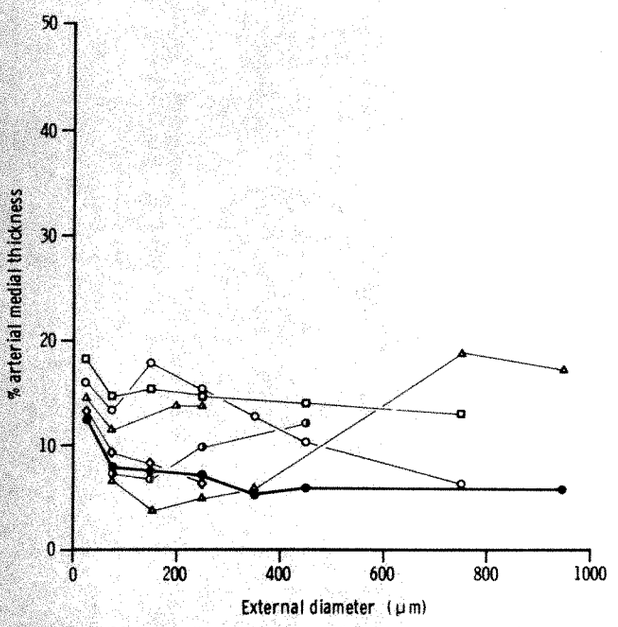

**FIGURE 6.** Mean percent arterial medial thickness related to external diameter (μm) in uninjected tissue from 5 children and 1 young adult, compared with normal findings. **Triangles,** indicate Case 5; **open circles,** Case 6; **squares,** Case 7; **diamonds,** Case 8; **half-shaded triangles,** Case 9; **half-shaded circles,** Case 10; **closed circles,** normal, 3 months to 9 years.

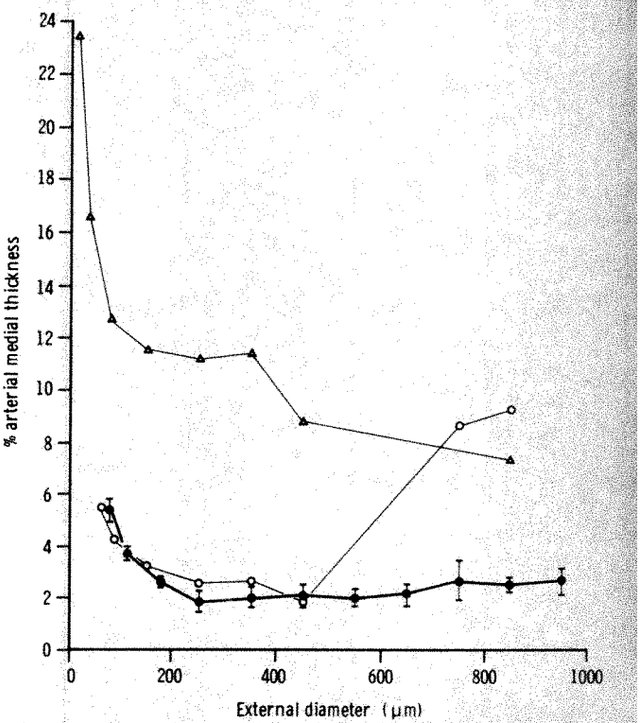

**FIGURE 7.** Mean percent arterial medial thickness related to external diameter (μm) in injected tissue from Cases 4 and 5, and from normal patients. **Triangles** indicate Case 4; **open circles,** Case 5; **closed circles,** normal, 4 months to 10 years, ±1 standard deviation.

**TABLE III Size and Number of Arteries Accompanying Peripheral Airways**

| Case | Age at Biopsy/ Death | Mean External Diameter (μm) | | | | Alveolar/ Arterial Ratio |
|---|---|---|---|---|---|---|
| | | TB | RB | AD | AW | |
| 1 | 3 mo | 66 | 37 | 17 | 15 | 14 |
| 2 | 5 mo | . . . | 44 | 23 | 14 | 17 |
| 3 | 6 mo | 63 | 38 | 26 | 15 | 10 |
| 4 | 5 mo | 88 | 55 | 35 | 23 | 10 |
| 5 | 2 yr | 80 | 58 | 34 | 24 | . . . |
| 6 | 5 yr | 81 | 52 | 37 | 25 | 10 |
| 7 | 5 yr | 85 | 45 | 31 | 20 | . . . |
| 8 | 7 yr | 147 | 76 | 41 | 23 | 10 |
| 9 | 9 yr | 120 | 71 | 42 | 20 | 12 |
| 10 | 21 yr | 71 | 59 | 38 | . . . | . . . |
| | | Normal Values | | | | |
| 4–6 mo | 3 | 66 | 44 | 26 | 18 | 10 |
| 2 yr | 2 | 95 | 62 | 42 | 23 | . . . |
| 5 yr | 2 | 109 | 74 | 41 | 22 | 10 |
| 8–9 yr | 2 | 109 | 76 | 47 | 23 | 10 |

AD = alveolar duct; AW = alveolar wall; RB = respiratory bronchiolus; TB = terminal bronchiolus.

9, the severe intimal fibrosis with occlusive change would have been classified as grade III disease. In Case 10, the severe fibrotic occlusive change with dilatation of alveolar duct and alveolar wall arteries indicated advanced stage III or early grade IV disease.

## Discussion

Four infants with a secundum ASD presented in cardiac failure; all had severe pulmonary hypertension and a marked increase in pulmonary arterial muscularity (Table IV). Only 1 infant survived closure of the defect, and he had the least increase in muscularity. In 4 children aged 5 to 9 years, pulmonary hypertension was less severe than in the infants and none had symptoms attributable to ASD. Nevertheless, in 2 patients examination of lung tissue showed severe obliterative pulmonary vascular disease, and of these 4 patients only 2 have had the defect closed successfully. One additional child did not fall into either group. Presentation was delayed until 2 years of age and was due to cyanosis, not heart failure. Only the preacinar arteries showed medial hypertrophy, but they also showed obliterative change; the more peripheral arteries were abnormally thin-walled. This child also did not survive surgery. Two patients, including the 21-year-old man, will not undergo surgery because of the severity of the pulmonary vascular disease. Thus, in only 3 of the 10 patients was it possible to close the defect successfully.

The present series of children with a secundum ASD and pulmonary hypertension is unusual because most such patients have, in addition, an obstructive left heart abnormality.[10] In most infants with a large isolated se-

**TABLE IV Summary of Results**

| Case | PAP/SAP | Pulmonary Arterial Muscularity | | Intraacinar Arteries | | Outcome |

A = medial atrophy; IF = intimal fibrosis; OB = obstructed branches; OC = occlusive fibrosis; Op = ASD closed successfully; PAP/SAP ratio of systolic pressures; ↑ and ↓ indicate increase and decrease with respect to normal for age; + = dead.

cundum ASD, pulmonary arterial pressure and resistance decrease normally after birth.[11] Pulmonary hypertension rarely develops before the third decade of life. During the last 10 years at the Hospital for Sick Children in London, an isolated secundum ASD was closed in 80 patients whose pulmonary arterial pressure was normal. Only 4 additional patients had pulmonary hypertension, 2 of whom are included in this study. The normotensive patients were 5 to 14 years old, and those with pulmonary hypertension were 6 months to 7 years of age. Also, pulmonary vascular resistance was elevated in all patients in the present study (including 3 infants); other series have included some infants in whom the resistance was not increased.[1,2]

Five of the 6 infants in the present study failed to respond to intensive medical therapy. Symptomatic infants can usually be managed conservatively, deferring surgery until the child is older,[1,4,12] but there are exceptions.[1,2]

Presentation of an ASD in infancy has been attributed to a primary abnormality of the pulmonary vasculature causing persistence of the fetal circulation, the ASD being incidental. In the present study, however, the presentation and clinical findings were unlike those seen in babies with persistent fetal circulation. The symptoms in the infants with an ASD were attributable to a high pulmonary blood flow due to a left-to-right shunt, whereas in babies with persistence of the fetal circulation, pulmonary blood flow is not increased. Instead, there is pulmonary hypoperfusion, and cyanosis is due to a right-to-left shunt through persistent fetal channels.[13] However, a prenatal increase in medial thickness and in the medial surface area of pulmonary vascular smooth muscle has been found in 3 fetuses with an ASD, suggesting that in some children the pulmonary circulation may be structurally abnormal before birth.[14] In the same study, a greater increase in muscularity occurred in 2 children who resembled the infants in the present series, dying in cardiac failure at 7 and 28 weeks of age.[14] After birth, it is probable that at least part of the increase in pulmonary arterial smooth muscle is secondary to an increase in pulmonary blood flow. The immature lung is more susceptible to an increase in flow than is the mature lung.[15–17]

In the present study the infants whose intrapulmonary arteries showed only medial hypertrophy were more sick and had a higher pressure than did most of the older patients, some of whom had more advanced pulmonary vascular disease. But the muscularized intraacinar arteries of the hypertensive lung have a different appearance in the first months of life from that seen in older patients. In the infant the smooth muscle cells are particularly large and plump, and the muscle coat is extremely thick relative to external diameter and severely narrows and sometimes even obstructs the lumen. It is not difficult to imagine that such change could produce greater elevation of resistance and a more labile pulmonary circulation than the less exuberant change found in older patients.

In this series the relation between the clinical and pathologic findings in the symptomatic infants and the relatively asymptomatic older children is not clear. One child did, however, present with heart failure at 3 months; at 4 years of age the child was clinically and pathologically similar to children of similar age, suggesting that with growth a high pulmonary arterial pressure and pulmonary arterial medial thickness may decrease. Other clinical studies suggest that this is so.[1,4,12] Perhaps in some children the hypertrophy of the media is too abundant to allow this to happen, and a hyperreactive pulmonary vascular bed is associated with uncontrolled heart failure and a higher operative mortality than is to be expected in the presence of a relatively simple cardiac defect. In 2 of the older children and in the man whose lung was biopsied at 21 years, the clinical and pathologic findings were similar to those seen in adults with an atrial septal defect and pulmonary hypertension, suggesting an accelerated progression of pulmonary vascular obliterative disease in these patients.

Vein wall thickness was increased in 5 cases in the present series. An increase in venous muscularity is frequently seen in the presence of arterial medial hypertrophy, and the relation is not understood. Left atrial pressure is frequently normal, as in the present study in which only Patient 2 showed a slight increase in mean pressure with respect to age.

The absence of pulmonary hypertension in the vast majority of patients with a secundum ASD is attributed to dilatation of the pulmonary arterial circulation, particularly of the proximal elastic pulmonary arteries. However, the arteries were dilated in only 1 child in the present study; despite the increase in arterial size, in this patient pulmonary hypertension was also severe. Of the remaining cases, in 6 the intraacinar arteries were reduced in either size or number. The same features of a restricted pulmonary vascular bed are found in infants and young children with a ventricular septal defect and pulmonary hypertension.[18]

The variation in response shown by different individuals to the presence of a large ASD is not understood. Individual susceptibility to the development of pulmonary hypertension is known to vary considerably.[19] Genetic factors are probably important in determining the amount of pulmonary vascular smooth muscle.[20] In the present series of children with a secundum ASD and pulmonary hypertension, there was no predominance of female patients. In a series of adult patients with an ASD who developed the Eisenmenger reaction, the female to male ratio, was 4 to 1.[21] Women also have a greater tendency than men to develop primary pulmonary hypertension in adult life. The greater tendency of female patients to develop the Eisenmenger reaction in ASD has been attributed to an underlying abnormality of the pulmonary vasculature akin to that present in women with primary pulmonary hypertension. There is no evidence to support this hypothesis in children.

The structural findings in the present study illustrate the difficulties of classifying pulmonary vascular disease in young children. In older patients, an increase in pulmonary arterial muscularity as the only structural

abnormality is associated with a mild increase in pulmonary arterial pressure and a favorable surgical outcome.[8] In infants, however, this is not always so, as the present study shows. Also, the same end result of increased muscularity and reduction in arterial size and number may represent a different type of structural change at different ages. Classification of pulmonary vascular change is necessary when describing the pathologic findings in a large population and when relating structural to hemodynamic findings. Particularly in childhood, however, it is preferable to describe precisely what is seen, rather than to use any system of classification which has certain clinical and prognostic associations.

**Clinical implications:** The rarity of pulmonary hypertension developing in children with an isolated secundum ASD is emphasized. Also, the majority of infants who do develop pulmonary hypertension and cardiac failure respond satisfactorily to medical treatment. The present study indicates that unfortunately it is the sick infants who have potentially reversible pulmonary vascular disease, while some asymptomatic older patients have more advanced disease which is less likely to reverse completely when the defect is closed.[22] Despite the high mortality in the present series, in symptomatic infants who fail to respond to intensive medical therapy the defect is best closed immediately, both to improve the clinical condition and to prevent the development of further pulmonary vascular damage.[4] In asymptomatic older children, if a diagnosis of a secundum ASD is made by 2-dimensional echocardiography alone, closure of the defect should not be postponed if there is any doubt that pulmonary arterial pressure is normal.

**Acknowledgment:** The author thanks the physicians, surgeons, and pathologists of the Kinderklinik der Medizinischen Hochschule, Hanover, the Royal Postgraduate Medical School, Guy's Hospital, the Brompton Hospital, the Royal Hospital for Sick Children, Glasgow, and colleagues at the Hospital for Sick Children, Great Ormond Street, London.

# Clinical Follow-Up Study of Paroxysmal Supraventricular Tachyarrhythmias After Operative Repair of a Secundum Type Atrial Septal Defect in Adults

ROBERT O. BRANDENBURG, Jr., MD, DAVID R. HOLMES, Jr., MD, ROBERT O. BRANDENBURG, MD, and DWIGHT C. McGOON, MD

**Adults with isolated secundum atrial septal defect (ASD) may present with paroxysmal atrial tachyarrhythmias. The clinical course of these rhythmic disturbances after correction of the ASD is unknown. Of 188 patients aged 44 years old or older with isolated ASD, 27 (14%) (mean age 52.7 years, range 44 to 71) had documented paroxysmal atrial tachyarrhythmias *preoperatively:* 16 had paroxysmal atrial fibrillation, 2 had atrial flutter, and 9 had supraventricular tachycardia. Among these 3 groups, there were no differences in age, sex, New York Heart Association class, duration of preoperative symptoms, mean right atrial and pulmonary arterial pressures, shunt size, atrial size, or follow-up period. After operative repair, follow-up data were available in all patients for a mean of 12 years (range 1.5 to 25). Of the 16 patients with preoperative paroxysmal atrial fibrillation, 14 (88%) continued to have increasingly frequent paroxysmal atrial fibrillation, culminating in sustained atrial fibrillation. In 1 of the 2 patients with paroxysmal atrial flutter, sustained atrial fibrillation developed. Of the 9 patients with preoperative paroxysmal supraventricular tachycardia, 5 had no further episodes of this arrhythmia postoperatively.**

Atrial septal defects (ASD) in adults may have various presentations ranging from no symptoms with abnormal findings on chest roentgenography or electrocardiography to severe disability with congestive heart failure and pulmonary hypertension. In addition, paroxysmal supraventricular tachyarrhythmias (atrial fibrillation, atrial flutter, and supraventricular tachycardia) are relatively common, particularly in older patients,[1–3] and may be the only presenting symptom. Operative repair of ASD has been well established as optimal treatment. Although improvement in hemodynamic and functional status after closure of an ASD is documented, the clinical course of paroxysmal supraventricular tachyarrhythmias after operation is not well known. To assess this condition, adult patients with secundum ASD who had documented paroxysmal tachyarrhythmias preoperatively were studied to determine the clinical course of the arrhythmias after operation.

## Methods

The records of all adult patients aged 44 years or older with ASD seen at the Mayo Clinic from 1955 to 1980 were reviewed. Patients with atrial defects other than the secundum type were excluded, as were patients with other accompanying congenital cardiac anomalies. Also excluded were patients with other possible causes of atrial arrhythmia, including mitral valve prolapse, hypertrophic cardiomyopathy, mitral or tricuspid regurgitation, pericarditis, Wolff-Parkinson-White syndrome, severe hypertension, and hyperthyroidism. Thirty-eight patients with chronic persistent atrial fibrillation before operation were also excluded. After these exclusions, there were 188 patients, 31 of whom had had paroxysmal supraventricular tachyarrhythmia (17%). Four of the 31 patients had no electrocardiographic documentation of the arrhythmia by the referring physician or at the Mayo Clinic before operation and they were excluded. The records of the remaining 27 patients form the basis of this report.

There were 7 men (aged 45 to 54 years at operation, mean 49) and 20 women (aged 44 to 71 years, mean 54). Ten patients (37%) were in class I, with paroxysmal tachycardia the only symptom; the remaining patients were in functional class II. As a group, the patients had had 2 to more than 400 subjective episodes of tachycardia (approximate mean 30 episodes per patient) from 1 month to more than 20 years before operation.

* All patients had sinus rhythm at the time of electrocardiographic recording.
C = complete; EAP = ectopic atrial pacemaker; I = incomplete; LAE = left atrial enlargement; MI = myocardial infarction pattern (anterior wall); RAD = right axis deviation; RAE = right atrial enlargement; RBBB = right bundle branch block; RVH = right ventricular hypertrophy.

Preoperative resting electrocardiograms were available in all patients (Table I). All demonstrated sinus rhythm, except 1 patient with an ectopic atrial pacemaker. The electrocardiograms were reviewed with regard to intraventricular conduction delay, ventricular hypertrophy, axis, and the presence of atrial enlargement.[4] Eighteen patients had preoperative cardiac catheterization at the Mayo Clinic, and 3 had it performed elsewhere. Pulmonary arterial mean pressure ranged from 14 to 46 mm Hg (mean 24) (19 patients), whereas the right atrial mean pressure ranged from 4 to 20 mm Hg (mean 7) (18 patients). Left-to-right shunts varied from 40 to 76% (mean 60%) (21 patients).

The operations were performed between August 1955 and February 1980. The defects in 5 patients operated on between August 1955 and November 1958 were closed with Ivalon® sponge using the "atrial well technique,"[5] whereas defects in 22 repaired after 1958 used direct suture. Right atrial size was estimated at operation on a scale of 1 (mild) to 6 (severe) in 25 patients.

## Results

**Preoperative arrhythmias:** Before operation, 16 patients had paroxysmal atrial fibrillation, 9 had paroxysmal supraventricular tachycardia,[6] and 2 had paroxysmal atrial flutter. Among these 3 groups, there were no significant differences in age, sex, New York Heart Association class, length of symptoms preoperatively, number of tachycardia episodes, mean pulmonary arterial and right atrial pressures, shunt size, type of surgical closure, right atrial size, or follow-up period.

**Early postoperative arrhythmias:** All 16 patients with preoperative paroxysmal atrial fibrillation had atrial fibrillation during the immediate postoperative period. At discharge, 10 patients had returned to sinus rhythm, whereas 6 continued to have atrial fibrillation. Five of the 6 patients later had transient conversion to normal sinus rhythm, whereas 1 patient had persistent atrial fibrillation (Fig. 1). In contrast, 7 of 9 patients with preoperative paroxysmal supraventricular tachycardia had no early postoperative arrhythmia (Fig. 2). One patient had two 4-hour episodes of paroxysmal supraventricular tachycardia on the first and second postoperative days, and the other patient had a 1-hour episode of paroxysmal supraventricular tachycardia on the second day. All 9 patients were in sinus rhythm at discharge. In both patients with preoperative paroxysmal atrial flutter, atrial flutter developed during the postoperative period. In 1 patient, it persisted at discharge.

**Follow-up study:** All patients with paroxysmal atrial fibrillation were followed up 3 to 25 years (mean 12). Of 16 patients with preoperative paroxysmal atrial fibril-

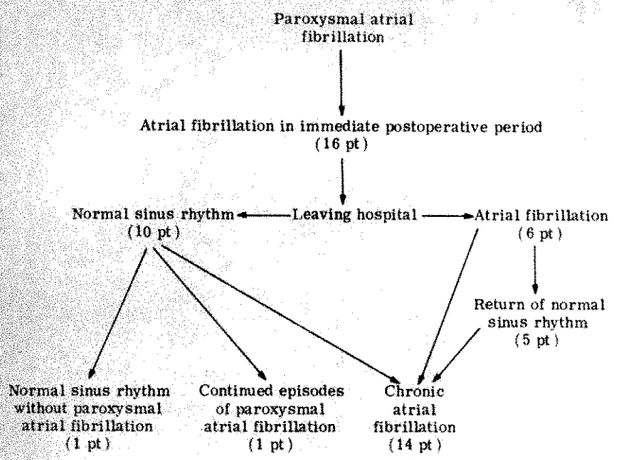

**FIGURE 1.** Course of patients (pt) with paroxysmal atrial fibrillation due to a secundum atrial septal defect.

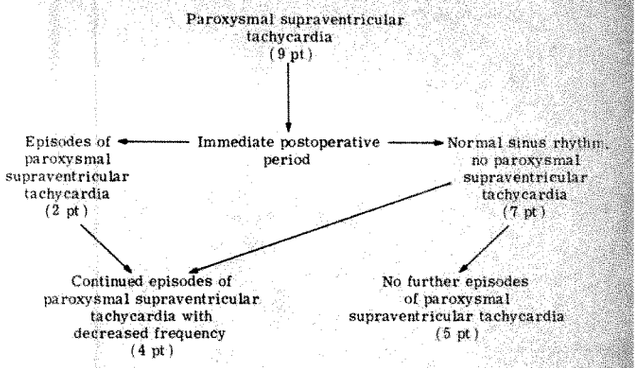

**FIGURE 2.** Course of patients (pt) with paroxysmal supraventricular tachycardia due to a secundum atrial septal defect.

lation, 14 continued to have increasingly frequent episodes postoperatively, finally culminating in chronic atrial fibrillation. Only 2 of the 16 patients are currently in sinus rhythm. One, a 51-year-old woman, now 13 years after operation, continues to have 1 or 2 episodes of atrial fibrillation per year and requires digitalis. Before operation, she had an 18-month history of paroxysmal atrial fibrillation. The other patient, a 51-year-old man with 7 episodes of atrial fibrillation before operation, has had no further episodes of tachycardia and requires no medication (Fig. 1).

The 9 patients with preoperative paroxysmal supraventricular tachycardia were followed from 1.5 to 23 years (mean 10). Five patients have had no further episodes of sustained paroxysmal supraventricular tachycardia postoperatively. As a group, the 5 patients before operation had from 7 to >100 episodes of tachycardia over 3 to 20 years (mean 9). Three of the 5 patients are currently taking no medication. Of the 9 patients having preoperative paroxysmal supraventricular tachycardia, 4 continued to have episodes of symptomatic tachycardia postoperatively, which gradually decreased in frequency. One patient, a 47-year-old woman, had 4 episodes during the first 5 postoperative years and has been asymptomatic for the past 6 years while on digitalis and propranolol therapy. This patient had had approximately 1 episode of tachycardia per month in the year before operation. A second patient, a 45-year-old man, had 1 episode 4 years after operation and then was asymptomatic for the next 7 years, after which he was lost to follow-up study. A third patient, a 53-year-old woman, has had approximately 10 episodes during the 7 years since operation, but none for the past year and is taking no medication. She had 6 episodes of paroxysmal supraventricular tachycardia during the 2 years before operation. The fourth patient, a 50-year-old woman, has also had approximately 10 episodes of paroxysmal supraventricular tachycardia while taking digitalis and propranolol during the 18 months since operation, but she felt that the frequency had greatly decreased compared with that before operation. Preoperatively, she had 1 to 2 episodes per week.

One of the 2 patients with preoperative atrial flutter had no further episodes for 12 years after operation. This 54-year-old man had a short history of arrhythmia preoperatively, with 2 disabling episodes of atrial flutter during 1 month. The other patient, a 45-year-old man, continued to have paroxysmal atrial flutter, which changed to chronic atrial fibrillation approximately 14 years after operation.

## Discussion

The favorable response to closure of an isolated ASD in older patients has been documented.[2–4,6–13] Many patients have a significant decrease in "palpitations" after operation.[12,13] However, no previous report has reviewed the patient's specific preoperative atrial tachyarrhythmia and follow-up clinical course after operation.

The supraventricular arrhythmias in these patients are not unexpected. Cardiovascular disorders with atrial enlargement, atrial distention, or increased atrial pressure are associated with an increased incidence of supraventricular arrhythmias, including paroxysmal atrial fibrillation, paroxysmal atrial flutter, and paroxysmal supraventricular tachycardia.[14–16]

The electrophysiologic mechanisms involved vary in terms of mechanisms of onset and perpetuation, depending on the particular rhythmic disturbance. In atrial fibrillation, multiple circus movements or wavelets of impulse transmission are probably involved.[15–18] The atrial fibrillation may be maintained, particularly in dilated atria, because the number of circuits is large, with less chance of spontaneous organization and termination.[15] Atrial dilatation is the common pathologic finding in patients who have atrial fibrillation of recent onset as compared with patients who have chronic atrial fibrillation in whom both atrial dilatation and atrial myocardial changes are found.[19] Atrial flutter is rare in the normal heart, usually being associated with atrial dilatation and conduction disturbances,[14,15] both of which are common in patients with ASD.

In contrast to the chaotic electrical activation in atrial fibrillation, paroxysmal supraventricular tachycardia

is more homogeneous. It is usually reentrant, although enhanced automatic mechanisms have been described.[20–24] The precise mechanism in our patients is unknown, as electrophysiologic studies were not performed. The increased incidence of atrial premature contractions associated with atrial dilatation could initiate reentrant tachycardia in the atrioventricular node or atrium and could account for the increased frequency of tachycardia.

The disparity in outcome between patients with preoperative paroxysmal atrial fibrillation and those with paroxysmal supraventricular tachycardia was striking. All but 2 patients who had atrial fibrillation eventually had sustained atrial fibrillation as compared with patients who had paroxysmal supraventricular tachycardia, whose rhythmic disturbance usually improved. There are several potential reasons for this difference. Although atrial size was similar in each group, the patients with atrial fibrillation may have had more extensive atrial disease, leading to continued lack of homogeneity with respect to conduction or refractoriness and resulting in sustained atrial fibrillation. Postoperative abolition of paroxysmal supraventricular tachycardia could be due to relief of atrial distention, thus reducing the tendency for atrial ectopy and thus decreasing the initiating mechanism for reentry. In addition, surgical incision might disrupt a portion of the reentrant circuit.

Irrespective of the anatomic and physiologic substrates involved, paroxysmal supraventricular tachyarrhythmia is relatively common in adults with ASD and may be the presenting symptom. The course of the arrhythmia postoperatively depends on its specific type. Paroxysmal atrial fibrillation tends to recur postoperatively, finally culminating in chronic atrial fibrillation. In contrast, paroxysmal supraventricular tachycardia can be expected to gradually improve or disappear after operation.

# Epicardial and Endocardial Activation in Patients With Endocardial Cushion Defect

ROBERT M. CAMPBELL, MD, MACDONALD DICK II, MD, PAUL HEES, BS, and DOUGLAS M. BEHRENDT, MD

**Epicardial and left ventricular endocardial activation were assessed in 5 patients (aged 4 months to 9.5 years) with endocardial cushion defect (ECD) during surgical repair. Epicardial activation was recorded from 40 to 47 sites over the epicardium; left ventricular endocardial activation was measured at 3 sites immediately after institution of cardiopulmonary bypass. Compared with the reported activation sequence in normal hearts, the pattern of excitation in hearts of patients with ECD was abnormal; epicardial excitation began at the left ventricular diaphragmatic surface and spread laterally and anteriorly over the anterobasal left ventricle. It then merged with right ventricular wavefronts ending along the right ventricular anterior atrioventricular groove and outflow tract. Left ventricular endocardial activation also occurred earliest in the diaphragmatic segment of the left ventricle with later wavefronts recorded laterally and anteriorly.**

**This study demonstrates, for the first time in human subjects, correlation between left ventricular epicardial and endocardial activation in patients with ECD. The data indicate that earliest endocardial and epicardial activation occurs at the left ventricular diaphragmatic segments of the heart, and are consistent with the known posterior and inferior displacement of the specialized atrioventricular conduction system in patients with ECD.**

The electrocardiographic and vectorcardiographic pattern of a left superior frontal plane mean QRS electrical axis with a counterclockwise loop, commonly observed in patients with both partial and complete forms of ECD, has been attributed by anatomic and pathologic studies[1,2] to posterior and inferior displacement of the atrioventricular node and His bundle along with early take-off of the posterior fascicles of the left bundle. Although data from previous electrophysiologic studies[3–5] mapping ventricular activation in patients with ECD are consistent with these anatomic observations, these studies recorded activation from the epicardial surface, but not the endocardial surface. The present study was designed to examine the sequence of both endocardial and epicardial activation of the left ventricle in patients with ECD and to correlate left ventricular epicardial activation with endocardial activation.

## Methods

Five children participated in this study (Table I), 3 females and 2 males aged 4 months to 9.5 years. Preoperative electrocardiograms were obtained in all 5 patients; vectorcardiograms were obtained in 2. Simultaneous electrocardiograms (using leads II, aVF, and $V_6$) and ventricular electrograms were recorded at surgery. All electrograms were recorded through bipolar electrodes (1 mm apart) connected to an Electronics for Medicine V1250A amplifier. The signal was filtered through a band width of 30 to 250 Hz, monitored on an Electronics for Medicine (VR12) switched-beam oscilloscope and recorded on photographic paper moving at 100 to 150 mm/s. Epicardial activation was recorded from 40 to 47 sites over the left and right ventricular epicardium, depending on individual heart size, before the initiation of cardiopulmonary bypass. After institution of cardiopulmonary bypass, the left ventricular endocardium was mapped through the atrial septal defect and the mitral valve from 3 sites: (1) the posterior paraseptal left ventricle, (2) the anterolateral left ventricular free wall, and (3) the anterior paraseptal left ventricle (Fig. 1). Esophageal temperature was maintained at 30 to 35°C during the study. The epicardial mapping procedure was completed within 15 minutes; left ventricular endocardial mapping was performed within 3 minutes after initiation of cardiopulmonary bypass. Activation times were measured from the onset of the QRS complex to the first fast action deflection to cross the isoelectric line in the electrogram; activation times in 5 to 15 consecutive sinus beats were measured and a mean activation time was computed. Values at

CCW = counterclockwise; ECD-C = endocardial cushion defect, complete; ECD-P = endocardial cushion defect, partial; MV = mitral valve.
* QRS axis within.

each mapping site in each patient were normalized by dividing the local activation time by the latest recorded ventricular activation time overall and then multiplied by 100. Due to elevation or retraction of the heart during intraoperative mapping, the QRS duration recorded on the surface electrocardiogram varied by approximately 15%; activation times were therefore corrected to baseline QRS duration.

**Definitions:** Epicardial breakthrough (EBT) is the site of emergence of a radially propagating wavefront at the epicardial surface, producing an island of early activation surrounded completely by points of later activation.[6] Latest epicardial activation (LEA) was defined as the latest recorded ventricular activation.[6]

## Results

The clinical, anatomic, and electrocardiographic data for each patient are summarized in Table I. The QRS duration ranged from 0.06 to 0.10 second (mean 0.08). The mean frontal plane QRS axis was superior in all cases, ranging from 320 to 250° (average 286). Vectorcardiograms were obtained in 2 patients (Cases 1 and 5). Both revealed counterclockwise frontal plane loops which became superior within 30 ms (30 and 28 ms, respectively). Analysis of scalar electrocardiograms on the remaining 3 patients indicated superior counterclockwise frontal plane loops.

**Epicardial map:** Epicardial maps were similar in all patients. No difference was observed in the map from the single patient (Case 5) with complete ECD. A typical example of local epicardial activation times (Patient 3) is depicted in Figure 2. The sequence of left ventricular activation was abnormal; the usual left ventricular EBT site in the basal area of the anterolateral left ventricle[6] was absent. In contrast, earliest left ventricular activation occurred at the diaphragmatic surface 15 ms after the onset of the electrocardiographic QRS complex. Subsequent left ventricular breakthrough was seen at 25 ms along the apical anterolateral left ventricular wall. Latest left ventricular activation was observed at the basal area of the anterolateral wall, 47 ms after the QRS onset; latest right ventricular activation, which represented the latest epicardial activation time recorded overall, was demonstrated in the anterior right atrioventricular groove at 61 ms.
